November 2015

Abstract

We discuss a variety of recent methodological advances that can be used to estimate mixed frequency factor-MIDAS models for the purpose of pastcasting, nowcasting, and forecasting. In order to illustrate the uses of this methodology, we introduce a new real-time Korean GDP dataset, and carry out a series of prediction experiments, using a two step approach. In a first step, we estimate common latent factors (i.e., diffusion indices) from 190 monthly macroeconomic and financial series using various estimation strategies. Second, we use these factors, along with standard variables measured at multiple different frequencies, in six varieties of factor-MIDAS prediction models. Our key empirical findings are that: (i) When using real-time data, factor-MIDAS prediction models outperform various linear benchmark models. Interestingly, the 'MSFE-best' MIDAS models contain no AR lag terms when pastcasting and nowcasting. Indeed, AR terms only begin to play a role in model specification at 6-month ahead horizons. (ii) Models that utilize only 1 or 2 factors are 'MSFE-best' at all forecast horizons, except those associated with so-called pastcasting and nowcasting. (iii) Real-time data are crucial for forecasting Korean GDP, and the use of 'first available' versus 'most recent' data 'strongly' affects model selection and performance. (iv) Recursively estimated models are almost always 'MSFE-best', models estimated using autoregressive interpolation dominate those estimated using other interpolation methods, and factors estimated using recursive principal component estimation methods have more predictive content than those estimated using a variety of other (more sophisticated) approaches. (v) Factor-MIDAS models which constitute the 'MSFE-best' models, across many forecast horizons, estimation schemes, and data vintages, perform best when factors are estimated recursively.

Keywords: nowcasting, forecasting, factor model, MIDAS.

JEL Classification: C53, G17.

1 Introduction

In this paper, we introduce a real-time Korean GDP dataset, and utilize this dataset, along with a larger monthly dataset including 190 variables, to nowcast and forecast GDP. Our nowcasting and forecasting models combine the mixed data sampling (MIDAS) framework of Ghysels et al. (2004), that allows for the incorporation of variables of differing frequencies, with variants of the principal components analysis (PCA) based common factor or diffusion index framework of Stock and Watson (2002). Suppose that the objective is to predict (or nowcast) GDP for 2016:Q2, say using a simple autoregressive model of order one (i.e., and AR(1) model). In a conventional setting where real-time data are not available, it is assumed that information up to 2016:Q1 is available at the time of the prediction is made, so that $\widehat{\text{GDP}}_{\text{2016:Q2}} = \hat{\alpha} + \hat{\beta}\text{GDP}_{\text{2016:Q1}}$, where $\hat{\alpha}$ and $\hat{\beta}$ are parameters estimated using maximum likelihood based on recursive of rolling data windows. In real-time context, however, this prediction model is not feasible to construct. For example, if the prediction is to be made in April or even May of 2016, then $\text{GDP}_{\text{2016:Q1}}$ is not yet available, even in preliminary release. In our forecasting experiments, all predictions are made with data which were truly available at the time the predictions were made. This allows us to simulate the real-time decision making process at the Bank of Korea.

Many key macroeconomic indicators in Korea are published by the Bank of Korea (BOK) with considerable delay and at low frequency. Key among these variables is Korean Gross Domestic Product (GDP), which is a component of the so-called system of national accounts (SNA), and has been published quarterly by the Bank of Korea since 1955. These GDP data are 'real-time', in the sense that they are regularly updated and revised. For example, the base year of SNA data is updated every 5 years. Additionally, since the first GDP release in the 1950s, there have been 11 definitional changes affecting the entire historical record. Finally, since 2005, 'first vintage' or first release real GDP has been regularly announced about 28 days after the end of the corresponding calendar quarter. Second vintage data is generally released about 70 days after the end of the quarter (at which time nominal GDP is also released). In approximate conjunction with this second release, the whole prior year of data is also revised and released. Finally, another revision is made approximately 15 months later.

In a real-time quarterly context, note that we can only observe information up to 2015:Q4, say, given that GDP is a quarterly series, and given the release lag discussed above. However, by utilizing additional series that are released at frequencies higher than quarterly, such as monthly variables, we might improve the performance of the above quarterly model, in real-time. It is in this sense that we examine the usefulness of mixed frequency modeling,

or MIDAS, in the context of real-time GDP prediction. Importantly, some of the MIDAS variables that we use, and in particular those available at the monthly frequency, are actually diffusion indices constructed by extracting common factors from our large monthly dataset. The use of higher frequency variables in our prediction models enables us to prediction current (and subsequent) quarter GDP at a monthly frequency. When these predictions are made during the same calendar quarter that we are in, such as when we are predicting GDP for 2016:Q2 and it is June 2016, then they are called nowcasts. Our main objective in this paper, in addition to our introduction of our new real-time Korean dataset, is to evaluate the relative performance of simple AR type models, MIDAS type models, diffusion index type models, and hybrids of all three varieties of models, in the context of real-time GDP prediction.

As alluded to in the above discussion, it is desirable to utilize as much information as possible, including monthly variables, for example, in order to address the issue of missing current information due to the gap between quarterly calendar dates and the publication of early data releases associated with these calendar dates. For example, it is well known that the most recent GDP data often contain the most information when predicting future GDP realizations. Since the most recent data are often not yet available in real-time, it is natural to ask whether available recent monthly data, and in particular those pertaining to calendar dates for which no GDP data are available, might serve a useful role in real-time nowcasting and forecasting.

There are several approaches to forecasting lower frequency variables using higher frequency variables. The first approach involves use of the so-called 'bridge' model, which aggregates short frequency variables with quarterly variables, such as GDP. This aggregation is called a 'bridge', and this method is commonly used by central banks, since implementation of the methods, and interpretation of results is straightforward (see e.g., Rünstler and Sédillot (2003), Golinelli and Parigi (2005) and Zheng and Rossiter (2006)). Indeed, this approach offers a very convenient solution for filtering variables of differing frequencies so that resultant dependent and explanatory variables using in prediction models are the same frequency. However, aggregation may lead to the loss of useful information. This issue has led to the recent development of alternative mixed frequency modeling approaches. One key approach, which is mentioned above, is called MIDAS. This approach involves use of a regression framework that allows for the direct use of variables sampled at different frequencies. MIDAS regression offers a parsimonious means by which lags of explanatory variables of differing frequencies can be utilized; and its use for macroeconomic forecasting is elucidated by Clements and Galvao (2008). Additional recent papers in this area of forecasting include Kuzin et al. (2011), who predict Euro area GDP, Ferrara and Marsilli (2013) who

predict French GDP, and Pettenuzzo et al. (2014), who discuss Bayesian implementation of MIDAS. One interesting feature of MIDAS is that the technique can readily be augmented by the inclusion of latent factors. These latent factors are based on an attempt, via the use of principal components, to distill into a single (or a small set) of variables, the common latent information contained in large-scale datasets.

In our forecasting experiments, we implement principal components in order to extract factors, also called diffusion indices, for inclusion in our forecasting models. These diffusion indices are constructed using non real-time monthly data. Hence, in order to retain the real-time feature of our experiments, only suitably lagged factors are used. For related evidence on the usefulness of factor thus constructed, see Stock and Watson (2012), Boivin and Ng (2005) and Kim and Swanson (2014a). For discussion of the combination of factor and MIDAS approaches, see Marcellino and Schumacher (2010). For an interesting application to the prediction of German GDP, see Schumacher (2007). A final issue, in the context of real-time prediction, is the staggered availability of variables that are published at the same frequency. For example, some of the predictor variables that we use are not available, even in the middle of the current month, while others are. Therefore, there are missing values at the end of the sample. This in turn leads to the so-called 'ragged-edge' data problem. In this paper, we tackle this issue following Wallis (1986) and Marcellino and Schumacher (2010), and estimate monthly common factors using PCA coupled with either: vertical data realignment, AR data interpolation, EM algorithm based missing value estimation, or a standard state space model. MIDAS prediction models are then implemented, yielding 'factor-MIDAS' predictions that are available at a monthly frequency for our quarterly GDP target variable.

This paper introduces a new real-time dataset, offers a first look at the issue of now-casting and forecasting real-time Korean GDP, discusses and synthesizes a wide variety of methodological approaches for doing so, and is meant as a starting point to examining the performance of real-time forecasting models using any of the burgeoning number of real time datasets that have been recently compiled by central banks and academic researchers. Future research question include the following: Are robust shrinkage methods such as the lasso and elastic net useful in the context of real-time prediction? Can predictions be improved by utilizing even higher frequency data than those used here, including high frequency financial data? In the context of high frequency data, are measures of risk such as so-called realized volatility useful as predictors? Finally, are alternative "sparse" diffusion index methodologies, such as sparse principal components analysis and independent component analysis (see. e.g. Kim and Swanson (2014b)).

Our findings can be summarized as follows. Real-time data makes a difference. In order

to properly utilize data in real-time, as it becomes available, common factors should be constructed, in a recursive real-time framework, and mixed frequency prediction models estimated. This leads to the best nowcast and forecasts, in a mean square forecast error sense. This finding is due in large part to the fact that many important economic indicators, such as CPI and Industrial Production are not only sampled at monthly or higher frequencies, but are useful for real-time GDP prediction.

When comparing MSFEs, only approximately 10% of models perform best when using vertical alignment or VA interpolation, with 90% favoring autoregressive or AR interpolation. Models estimated using rolling data windows are only 'MSFE-best' at 3 forecast horizons, when using 'first available' data, and are never 'MSFE-best' when 'most recent' data are used. Given the common preference amongst empirical researchers to use 'most recent' data, it is clear that in the case of Korean GDP, recursive estimation is preferred, perhaps implying that any structural instability in our 'MSFE-best' models is mild. With regard to the number of factors to specify in prediction models, either 1 or 2 factors, at most, are needed when the prediction horizon in more than 3 months ahead. On the other hand, for horizons -1 to 3 (i.e. all pastcasts and nowcasts), the evidence is more mixed. While 1 or 2 factors are selected around 1/2 of the time, 5 or 6 factors are also selected around 1/2 of the time. Interestingly, there is little evidence that using an intermediate number of factors is useful. One should either specify a very parsimonious 1 or 2 factor models, or one should go with our maximum of 5 or 6. In summary, forecast horizon matters, in the sense that when uncertainty is more prevalent (i.e., longer forecast horizons), then parsimony is the key ingredient to factor selection, and any more than 1 or 2 factors leads to worsening predictive performance.

Turning to the findings of our prediction experiments, note that when evaluation is carried out with 'first available' data, for pastcasting and nowcasting, factor-MIDAS models without AR terms as well as other benchmark models do not work well, regardless of the number of factors. In these cases, pure autoregressive models dominate, in terms of MSFE. This suggests that for short forecast horizons, the persistence of Korean GDP growth is strong, and well modeled using linear AR components. Indeed, in many of these cases, our simplest linear AR models are 'MSFE-best'. As the forecast horizon gets longer, simple linear models are no longer 'MSFE-best', and models without AR terms in some cases outperform models with AR terms. This is interesting, as it suggests that uncertainty in autoregressive parameters does not carry over to other model parameters, as the horizon increases, and the role for MIDAS thus increases in importance. However, when 'most recent' real-time data are used in our prediction experiments, the reverse holds. Namely, more complicated MIDAS models dominate at all forecast horizons, and AR terms are only useful at longer forecast horizons

(of at least 6 months). Given that 'most recent' data are those that are most often used by empirical researchers, we thus have direct evidence of the usefulness of factor-MIDAS coupled with real-time data for forecasting Korean GDP.

The rest of the paper is organized as follows. Our real-time Korean GDP dataset is introduced in Section 2. Section 3 describes how to estimate common factors using recursive and non-recursive PCA methods, and discusses approaches to addressing ragged-edge data. The MIDAS framework for nowcasting and forecasting is discussed in Section 4. Finally, Section 5 presents the results of our forecasting experiments, and Section 6 concludes the paper.

2 Real-Time Data

When constructing real-time datasets, both the data vintage (which 'release' of data we are referring to, and when it was released) and the calendar date (the actual calendar date to which the data pertain) matter. Figure 1 depicts this relationship for Korean GDP.

[Insert Figure 1 here]

Moreover, when constructing growth rates (e.g. log differences) of GDP, data vintage is clearly relevant. It is thus important to carry forward a consistent and sensible notation, when using real-time data in model specification and estimation Let Z be the level of a variable and z be the log difference thereof. Define

$$z_t^{(1)} = \ln Z_t^{1st} - \ln Z_{t-h}^{1st} \tag{1}$$

where Z_t^{1st} is the first release of Z_t at for calendar date t, and h refers here to the difference taken (i.e. $h = 1$ for first log differences, and $h = 4$ for 4th (annual) log differences). In practice, $z_t^{(1)}$ is not commonly used in empirical analysis, since, at calendar date t, a more recent release than $1st$ may be available for Z_{t-h}. If Z_{t-h} has already been revised once, then use of this updated data may be preferred, leading to the following definition, for $h = 1$:

$$z_t^{(2)} = \ln Z_t^{(1)} - \ln Z_{t-1}^{(2)} \tag{2}$$

If we define the growth rate as year-to-year, based on the schedule of GDP announcements in Korea, the growth rate corresponding to the above definition (i.e., where the most recently available data are used) is

$$z_t^{(3)} = \ln Z_t^{(1)} - \ln Z_{t-4}^{(3)} \tag{3}$$

In summary, when we are at calendar date t, the latest observation available for date t is the first release. For our real-time analysis, wherein we update our predictions at a monthly frequency, it is necessary to specify monthly subscript for data vintage. In particular, define:

$$ {}_{t_m}y_{t_q} = {}_{t_m}Y_{t_q} - {}_{t_m}Y_{t_q-d} \tag{4} $$

where Y and y stand for the log level and the growth rate of GDP, d is a length of the difference. For example, $d = 4$ when we specify year-on-year growth rates. Suppose that t_m =2016:05 and t_q is 2016:Q1. In practice, we do not Y for 2016:Q2, as t_m =May 2016. In light of this, we redefine (4), taking into account the publication lag, k, as follows:

$$ {}_{t_m}y_{t_q} = {}_{t_m}Y_{t_q-k} - {}_{t_m}Y_{t_q-k-d} $$

Therefore, the year-on-year growth rate of GDP for 2016:Q1 at May 2016 as

$$ {}_{2014:05}y_{2016:Q1} = {}_{2014:05}Y_{2016:Q1} - {}_{2014:05}Y_{2015:Q1} \tag{5} $$

Note that ${}_{2014:05}y_{2016:Q2}$ is not available, in practice. In light of this, we add the release version by adding a superscript, as follows:

$$ {}_{2014:05}y^{(3)}_{2016:Q1} = {}_{2014:05}Y^{(1)}_{2016:Q1} - {}_{2014:05}Y^{(3)}_{2015:Q1}, \tag{6} $$

where the superscript corresponds to the release (e.g. 3 corresponds to a third release or vintage). Figure 2 depicts the construction of real-time GDP growth rates.

[Insert Figure 2 here]

Putting this all together, our real-time nomenclature for GDP is:

$$ {}_{t_m}y^{(3)}_{t_q-k} \tag{7} $$

In practice, data such as ${}_{t_m}y^{(1)}_{t_q-k}$ and ${}_{t_m}y^{(2)}_{t_q-k}$ are feasible to construct, but are of little use if forecasters are interested in year-on-year growth rates. Equation (7) defines the datum that is observable at time t_m, and we shall call this the first vintage growth rate of GDP.

For ease of exposition, we henceforth let Y be the growth rate, not the GDP level. Hence, ${}_{t_m}Y^{(1)}_{t_q-k}$ denotes the first vintage growth rate of GDP, instead of (7). Accordingly, ${}_{t_m+m}Y^{(i)}_{t_q-k}$ is the $i-$th vintage growth rate for calendar date t_q-k at time t_m+m, where m is the feasible month for which $i-$ th vintage data are available. In the sequel, when the superscript for

the vintage is omitted, we mean first vintage.

Given the above notation, we can specify forecast models using real-time data. Suppose that we predict h_q steps ahead at time t_m, using an AR(1) model. Then, the prediction model is:

$$ {}_{t_m}Y_{t_q-k+h_q} = \alpha + \beta_{h_q} \cdot {}_{t_m}Y_{t_q-k} + \epsilon_{t_q} \tag{8} $$

Here, vintage notation is omitted for brevity. Note that we forecast h_q periods ahead at time t_m (or t_q), but we do not have real-time information up to t_q. Therefore, there is k lags in the explanatory variables. Equation (8) is one of our benchmark forecasting models. Assume that we are at time t_m in the first month of the quarter, t_q. If there is a publication lag, $k = 1$, we 'pastcast' a value for $t_q - k$, 'nowcast' a present value of GDP for t_q, and 'forecast' a future value of GDP for $t_q + h_q$ periods ahead.

3 Real-Time Data Description

We have collected real-time Korean GDP beginning with the vintage available in January 2000. The calendar start date of our dataset is 1970:Q1, and data are collected through June 2014. As discussed in the introduction, first release GDP is announced 28 days after the end of the quarter, the second release is announced 70 days subsequent to the end of the quarter, and the third release is made available 50 days after a calendar year has passed. Finally, a fourth release is made available a full year after a calendar date has passed. This rule has been fixed since 2005. Before then, release dates were relatively irregular, although the first release was usually around 60 days after the end of the quarter, and the second release was around 90 days after the end of the quarter. Even though GDP is finalized after 2 years, there are several definitional changes, as well as regular base-year changes that affect our dataset. The revision history for Korean GDP is depicted in Figure 3. Panel (a) of Figure 3 shows the growth rate of GDP by vintage. The plot denoted as '1st' is first release GDP, and so on. In Panel (b), revision errors are depicted. Plots denoted as '2nd', '12th' and '24th' all refer to differences relative to the first release. Prior to the 1990's, the differences were relatively large; with notable narrowing of these 'revision errors' more recently. It seems that along with the imposition of stricter release and announcement protocol, early releases have become more accurate. Panel (c) of Figure 3 depicts how GDP for certain calendar dates (i.e., 2001:Q1, 2003:Q1 and 2005:Q1) has evolved across releases. The GDP release dynamics observable in Panels (a), (b) and (c) is indicative of the fact that policy decision-making should carefully account for the real-time nature of GDP data. Panel (d) contains a histogram of first revision errors, which are the difference between first and second releases,

over time. Interestingly, the first vintage is biased, as indicated by the asymmetric nature of the histogram. This suggests that the revision error history may be useful for prediction.

[Insert Figure 3 here]

Our monthly predictor dataset is not measured in real-time, as it was infeasible to construct a real-time dataset for the 190 variables utilized in our prediction experiments. The monthly data used are discussed in Kim (2013). These data have been categorized into 12 groups: interest rates, imports/exports, prices, money, exchange rates, orders received, inventories, housing, retail and manufacturing, employment, industrial production, and stocks. We extend this monthly dataset through June 2014 in the current paper. Moreover, all variables are transformed to stationarity, and the final dataset resembles quite closely the well-known Stock and Watson dataset which has been extensively used to estimate common factors for the U.S. economy. For complete details, see Kim (2013).

4 Estimating Common Factors

We estimate common latent factors (i.e., diffusion indices) from the 190 monthly macroeconomic and financial series discussed above. Thereafter, we use these factors, along with standard variables measured at multiple different frequencies, in MIDAS prediction regressions. One conventional way to estimate common factors is via the use of principal component analysis (PCA). In order to avoid computational burdens associated with matrix inversions, and in order to simulate a 'real-time' environment, we use a variant thereof, called recursive PCA, following Peddaneni et al. (2004). In this section, we discuss these and other key details associated with factor estimation, in our context.

4.1 Constructing factors using ragged-edge data

Since we use real-time GDP, it is critical to match monthly data availability with GDP release vintages. In particular, some of our monthly variables are not available at certain calendar dates even though new vintages of GDP have been released by said calendar dates. For example, the consumer price index for the previous month is released early in the current month, whereas the producer price index is released in the middle of the month. In between these releases, new vintages of GDP are often released. This is called a ragged-edge data problem. Suppose that we collect a large number of monthly data (i.e., an N-dimensional vector of data at each point in time), say X_{t_m} where time index t_m denotes the monthly

frequency. Assume that the monthly observations have a factor structure, as follows:

$$X_{t_m} = \Lambda F_{t_m} + \xi_{t_m}, \tag{9}$$

where the r-dimensional factor vector is denoted by $F_{t_m} = \left(f'_{1,t_m}, \ldots, f'_{r,t_m}\right)$, and $r << N$. Note that we do not have monthly indicators in real-time, so that there is no prefix subscript in 9. The common components of X_{t_m} consists of F_{t_m} and the $(N \times r)$ loading matrix Λ. The idiosyncratic components, ξ_{t_m}, are that part of X_{t_m} not explained by the factors. Let data matrix X be a balanced one with dimension $T_m \times N$. Various way to estimate the factors have been suggested in the literature. The most widely used methods are based on static PCA, as in Stock and Watson (2002); or dynamic PCA, as in Forni et al. (2005).

Unfortunately, PCA is based on an eigenvalue/eigenvector decomposition of the covariance matrix of X_{t_m}, which requires inversion of this matrix. This means that the dataset must be 'completed' (i.e., not ragged). Therefore, we need to resolve ragged-edge problem in order to obtain PCA estimators of the factors. In this paper, we use *vertical alignment* and *AR interpolation* for missing values. Another convenient way to solve the ragged-edge problem is proposed by Stock and Watson (2002), who use the EM algorithm together with standard PCA. One can also write the factor model in state-space form in order to handle missing values at the end of each variables' sample, following Doz et al. (2012) (these authors use a Kalman filter and smoother for estimation).

Vertical alignment (VA) interpolation of missing data:

The simple way to solve the ragged-edge problem is to simply make unbalanced datasets balanced. Assume that variable i is released with a k_i month publication lag. Thus, given a dataset in period T_m, the final observation available of this time series is for period $T_m - k_i$. The realignment proposed by Altissimo et al. (2010) is:

$$\tilde{X}_{i,t_m} = X_{i,t_m - k_i}, \tag{10}$$

for $t_m = k_i + 1, \cdots, T_m$. Applying this procedure for each series, and harmonizing at the beginning of the sample, yields a balanced dataset, $\tilde{X}_{t_m}$, for $t_m = \max\left(\{k_i\}_i = 1^N\right) + 1, \cdots, T_m$. Given this new dataset, PCA can be immediately implemented. Although easy to use, a disadvantage of this method is that the availability of data determines dynamic cross-correlations between variables. Furthermore, statistical release dates for each variables are not the same over time, for example, due to major revisions.

AR interpolation of missing data:

As an alternative to vertical alignment, we use univariate autoregressive models for individual monthly indicators, X_i. Namely, specify and estimate the following models:

$$X_{i,t} = \sum_{s=1}^{p_i} \rho_s X_{i,t-s} + u_{i,t}, \qquad i = 1, \ldots, k, \tag{11}$$

where p_i is the lag length (selected using the Schwartz Information Criterion - SIC), coefficients ρ are estimated using maximum likelihood, and $u_{i,t}$ is a white noise error term. This AR method depends only on the univariate characteristic of the variable in question, and not on the broader macroeconomic environment from within which the data are generated. However, it is very easy to implement and is an intuitive approach. In the sequel, we consider both approaches to the ragged-edge problem.

EM algorithm for estimating missing data:

The ragged-edge problem essentially concerns estimating missing values. Stock and Watson (2002) propose using the EM algorithm to replace missing values and carry out PCA. The EM algorithm is initialized with an estimate of the missing data, which is usually set equal to the unconditional mean of the series (this is also the approach that we use). Then use the completed dataset to estimate factors using ordinary PCA. This algorithm is repeated in two steps, the E-step and the R-step. We briefly explain these steps, and the reader is refereed Schumacher and Breitung (2008) for details. Consider a dataset, X_{t_m}, and pick variable i, say $X_i = (x_{i,1}, ..., x_{i,t_m})'$. Suppose that variable i has missing values due to publication lags. Set $X_i^{obs} = P_i X_i$, where P_i represents the relationship between the full vectors and the ones with missing values. If no missing values are found, then P_i is the identity matrix. As we only observe a subset of X, initialize the EM algorithm by replacing missing values with the unconditional mean of X_i^{obs}, yielding initial estimates of factors and loadings (using PCA), say F^0 and Λ^0. Now iterate this procedure. In the j-th iteration, the E-step updates the estimates of the missing observations using the the expectation of the variable X_i conditional on X_i^{obs}, with factors and loading from the $j-1th$ iteration, F^{j-1} and Λ^{j-1}, as follows:

$$X_i^j = F^{j-1}\Lambda^{j-1} + P_i' \left(P_i' P_i\right)^{-1} \left(X_i^{obs} - P_i F^{j-1} \Lambda_i^{j-1}\right), \tag{12}$$

Run the E-step for all i, in each iteration. The M-step involves re-estimating the factors and loadings using ordinary PCA. Continue until convergence is achieved.

State-space model (Kalman filtering) for estimating missing data:

Another popular approach for estimating factors from large datasets is state-space approach based on Doz et al. (2012) and Giannone et al. (2008). The factor model represented

by state-space form is based on the 9, with factors is represented in AR form, as follows:

$$\Psi(L_m)F_{t_m} = \mathbf{A}\eta_{t_m}, \tag{13}$$

where $\Psi(L_m)$ is a lag polynomial, given by $\sum_{i=1}^{p} \Psi_i L_m^i$, and η_{t_m} is an orthogonal dynamic shock. The state-space form can be easily estimated via maximum likelihood (ML). Doz et al. (2012) propose using quasi-ML for large datasets, when conventional ML is not feasible. In particular, as ML estimation involves initialization of factors based on the use of ordinary PCA, one needs a completed data matrix. Marcellino and Schumacher (2010) remove missing values from the end of sample to make it balanced, and estimate initial factors using ordinary PCA. In our forecasting experiments, initial factors are extracted from the completed matrix that is completed using VA and AR interpolation. Then likelihoods are estimated and evaluated using the Kalman filter. More specifically, given an initial set of factors, estimate loadings by regressing X_{t_m} on the factors. Then, obtain the covariance matrix of the idiosyncratic part from 9, $\sum_{\xi}$, where $\xi_{t_m} = X_{t_m} - \Lambda F_{t_m}$. Now, estimate a vector AR(p) on the factors, F_{t_m}, yielding the coefficient matrix, $\Psi(L)$, and the residual covariance matrix, $\sum_{\varsigma}$ where $\varsigma_{t_m} = \Psi(L_m)F_{t_m}$. Let V be the eigenvectors corresponding to E, the diagonal matrix whose diagonal elements are the eigenvalues in descending order, and zero otherwise. Then set $P = VE^{-1/2}$. As a final step, the Kalman smoother is then used to yield new estimates of the factors.

4.2 Recursive principal component analysis

Principal component analysis is a well known technique that has been widely used to estimate factor or diffusion index models in large data environments (see. e.g. Kim and Swanson (2014b) and the references cited therein). Moreover, PCA is quite convenient as it uses standard eigenvalue decompositions of data covariance matrices. However, this requires extensive matrix operations that may time consuming in certain real-time environments. In light of this, recursive PCA (denoted RPCA) has been proposed by Peddaneni et al. (2004), who suggest calculating eigenvectors and eigenvalues iteratively using a first order matrix perturbation of the covariance matrix estimate with every new sample obtained. This is clearly the natural approach in real-time settings wherein new data arrive and need to be incorporated into prediction models. Moreover, it involves less burden, computationally, when estimating high dimensional covariance matrices.

Suppose that the factor, F, given in (9), is estimated using standard principal component analysis, following Stock and Watson (2012) or Kim and Swanson (2014b), say. Principal

components (factors) in this context are linear combinations of variables that maximize the variance of the data, and there is no guarantee that factor loadings are stationary at each point in time, particularly with large datasets. For example, the loadings from PCA at time t and $t+1$ may have different signs, even though both factors span same sample space. Additionally, the whole data covariance is calculated at each point in time using this method, as new data arrives from t to $t+1$.

Recursive PCA attempts to address these issues by recursively updating factor loadings to incorporate newly introduced data, using the first order matrix perturbation of the covariance (or correlation) matrix. This is convenient, since we do not need to treat the entire dataset and calculate the whole covariance matrix of data with the arrival of each new datum. Without loss of generality, consider a standardized random vector at time t, x_t with dimension n. Our aim is to find the principal components of x at time t. To begin, define the covariance (or correlation) matrix of x as:

$$\boldsymbol{R}_t = \frac{1}{t}\sum_{i=1}^{t} x_i x_i' = \frac{t-1}{t}\boldsymbol{R}_{t-1} + \frac{1}{t}x_t x_t'. \tag{14}$$

If $\boldsymbol{Q}$ and $\boldsymbol{\Lambda}$ are the orthonormal eigenvector and diagonal eigenvalue matrices of $\boldsymbol{R}$, then $\boldsymbol{R}_t = \boldsymbol{Q}_t\boldsymbol{\Lambda_t}\boldsymbol{Q}_t'$ and $\boldsymbol{R}_{t-1} = \boldsymbol{Q}_{t-1}\boldsymbol{\Lambda}_{t-1}\boldsymbol{Q}_{t-1}'$. We can rewrite (14) as:

$$\boldsymbol{Q}_t\left(t\boldsymbol{\Lambda}_t\right)\boldsymbol{Q}_t' = x_t x_t' + \left(t-1\right)\boldsymbol{Q}_{t-1}\boldsymbol{\Lambda}_{t-1}\boldsymbol{Q}_{t-1}'. \tag{15}$$

If we let $\alpha_t = \boldsymbol{Q}_{t-1}'x_t$, (15) can be written as:

$$\boldsymbol{Q}_t\left(t\boldsymbol{\Lambda}_t\right)\boldsymbol{Q}_t' = \boldsymbol{Q}_{t-1}\left[\left(t-1\right)\boldsymbol{\Lambda}_{t-1} + \alpha_t\alpha_t'\right]\boldsymbol{Q}_{t-1}'. \tag{16}$$

If $\boldsymbol{V}_t$ and $\boldsymbol{D}_t$ are the orthonormal eigenvector and diagonal eigenvalue matrices of $\left(t-1\right)\boldsymbol{\Lambda}_{t-1}+\alpha_t\alpha_t'$, then:

$$\left(t-1\right)\boldsymbol{\Lambda}_{t-1} + \alpha_t\alpha_t' = \boldsymbol{V}_t\boldsymbol{D}_t\boldsymbol{V}_t'. \tag{17}$$

Therefore,

$$\boldsymbol{Q}_t\left(t\boldsymbol{\Lambda}_t\right)\boldsymbol{Q}_t' = \boldsymbol{Q}_{t-1}\boldsymbol{V}_t\boldsymbol{D}_t\boldsymbol{V}_t\boldsymbol{Q}_{t-1}'. \tag{18}$$

By comparing both sides of (18), the recursive eigenvector and eigenvalue update rules turn out to be

$$\begin{aligned}\boldsymbol{Q}_t &= \boldsymbol{Q}_{t-1}\boldsymbol{V}_t\\ \boldsymbol{\Lambda}_t &= \boldsymbol{D}_t/t.\end{aligned} \tag{19}$$

However, the problem remains as to how to estimate the eigenvector and eigenvalue of $(t-1)\,\boldsymbol{\Lambda}_{t-1} + \alpha_t\alpha_t'$, which is identical to finding $\boldsymbol{V}_t$ and $\boldsymbol{D}_t$. It is very difficult to find the solution of $\boldsymbol{V}_t$ and $\boldsymbol{D}_t$ analytically, and so Peddaneni et al. (2004) use first order perturbation analysis. Consider the following sample perturbation to the eigenvalue matrix, $(t-1)\,\boldsymbol{\Lambda}_{t-1} + \alpha_t\alpha_t'$. When t is large, this matrix is basically a diagonal matrix, which means that $\boldsymbol{D}_t$ will be close to $(t-1)\,\boldsymbol{\Lambda}_{t-1}$ and $\boldsymbol{V}_t$ will be close to the identity matrix $\boldsymbol{I}$. The matrix $\alpha_t\alpha_t'$ is said to perturb the diagonal matrix $(t-1)\,\boldsymbol{\Lambda}_{t-1}$, as a result of which $\boldsymbol{D}_t = (t-1)\,\boldsymbol{\Lambda}_{t-1} + \boldsymbol{P}_\Lambda$ and $\boldsymbol{V}_t = \boldsymbol{I} + \boldsymbol{P}_V$, where $\boldsymbol{P}_\Lambda$ and $\boldsymbol{P}_V$ are small perturbation matrices. Once we find these perturbation matrices, we can solve the problem. Let $\boldsymbol{\Lambda} = (t-1)\,\boldsymbol{\Lambda}_{t-1}$, then

$$\begin{aligned}
\boldsymbol{V}_t\boldsymbol{D}_t\boldsymbol{V}_t' &= (\boldsymbol{I}+\boldsymbol{P}_V)\,(\boldsymbol{\Lambda}+\boldsymbol{P}_\Lambda)\,(\boldsymbol{I}+\boldsymbol{P}_V)' \\
&= \boldsymbol{\Lambda} + \boldsymbol{\Lambda}\boldsymbol{P}_V' + \boldsymbol{P}_\Lambda + \boldsymbol{P}_\Lambda\boldsymbol{P}_V' + \boldsymbol{P}_V\boldsymbol{\Lambda} + \boldsymbol{P}_V\boldsymbol{\Lambda}\boldsymbol{P}_V' + \boldsymbol{P}_V\boldsymbol{P}_\Lambda + \boldsymbol{P}_V\boldsymbol{P}_\Lambda\boldsymbol{P}_V' \qquad (20)\\
&= \boldsymbol{\Lambda} + \boldsymbol{P}_\Lambda + \boldsymbol{D}\boldsymbol{P}_V' + \boldsymbol{P}_V\boldsymbol{D} + \boldsymbol{P}_V\boldsymbol{\Lambda}\boldsymbol{P}_V' + \boldsymbol{P}_V\boldsymbol{P}_\Lambda\boldsymbol{P}_V'
\end{aligned}$$

Substituting this equation into (17), and assuming that $\boldsymbol{P}_V\boldsymbol{\Lambda}\boldsymbol{P}_V'$ and $\boldsymbol{P}_V\boldsymbol{P}_\Lambda\boldsymbol{P}_V'$ are negligible, we have that:

$$\alpha_t\alpha_t' = \boldsymbol{P}_\Lambda + \boldsymbol{D}\boldsymbol{P}_V' + \boldsymbol{P}_V\boldsymbol{D}. \qquad (21)$$

The orthonormal of $\boldsymbol{V}$ allows an additional characterization of $\boldsymbol{P}_V$. Substituting $\boldsymbol{V} = \boldsymbol{I} + \boldsymbol{P}_V$ into $\boldsymbol{V}\boldsymbol{V}' = \boldsymbol{I}$, and assuming that $\boldsymbol{P}_V\boldsymbol{P}_V' \approx 0$, we have $\boldsymbol{P}_V = -\boldsymbol{P}_V'$. Thus, combining the fact that the $\boldsymbol{P}_V$ is antisymmetric and $\boldsymbol{P}_\Lambda$, and $\boldsymbol{D}_t$ are diagonal, we can write the solution as follows:

$$\alpha_i^2 = (i,i)^{th} \text{ element of } \boldsymbol{P}_\Lambda \qquad (22)$$

$$\frac{\alpha_i\alpha_j}{\lambda_j + \alpha_j^2 - \lambda_i - \alpha_i^2} = (i,j)^{th} \text{ element of } \boldsymbol{P}_V,\ i \neq j \qquad (23)$$

$$0 = (i,i)^{th} \text{ element of } \boldsymbol{P}_V$$

This leads to the following algorithm.

Algorithm: Recursive Principal Component Analysis

At time t, we have the covariance matrix that was available at time $t-1$, $\mathbf{R}_{k-1}$ and therefore we can obtain eigenvalues and eigenvectors, collected into the following matrices: Λ_{t-1} and $\mathbf{Q}_{k-1}$. The following algorithm is implemented at each observation.

1. With a new data, x_t, calculate $\alpha_t = \mathbf{Q}_{t-1}'x_t$.

2. Use (22), and find the perturbation matrices, $\mathbf{P}_V$ and $\mathbf{P}_\Lambda$.

3. Estimate the eigenvector matrix, $\tilde{\mathbf{Q}}_t = \mathbf{Q}_{t-1}\left(I + \mathbf{P}_\Lambda\right)$.

4. Standardize $\tilde{\mathbf{Q}}_t$ using $\hat{\mathbf{Q}}_t = \tilde{\mathbf{Q}}_t\tilde{\mathbf{S}}_t$, where $\tilde{\mathbf{S}}_t$ is a diagonal matrix containing the inverse of the norms of each column of $\tilde{\mathbf{Q}}_t$.

5. Estimate the eigenvalue, $\hat{\Lambda}_t = \hat{\mathbf{Q}}_t'\mathbf{R}_t\hat{\mathbf{Q}}_t$.

In this paper, we estimate factors from monthly indicators, and address the ragged-edge problem by introducing VA and AR interpolation, as well as via the use of factor estimation methods including the EM algorithm and state-space model. RPCA is used in order to reduce computational issues associated with estimating factors using large and growing datasets. However, standard or ordinary PCA (called OPCA) is also used, for comparison purposes. These methods yield the factors used in our factor-MIDAS prediction models, which are discussed in the next section.

5 Nowcasting and Forecasting Using MIDAS

5.1 Basic MIDAS model

The MIDAS approach with factors is developed by Clements and Galvao (2008, 2009). Additionally Marcellino and Schumacher (2010) introduce factor-MIDAS in the context of large macroeconomic datasets. Factor-MIDAS is essentially conventional MIDAS augmented to include explanatory variables that are common factors extracted from higher frequency variables and datasets. More specifically, suppose that Y_{t_q} is sampled at a quarterly frequency. Let X_{t_m} be sampled m times faster - for example, if it is sampled monthly, $m = 3$. Then the basic MIDAS model for forecasting h_q quarters ahead is:

$$Y_{t_q+h_q} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right)\hat{F}_{t_m}^{(3)} + \varepsilon_{t_q}, \tag{24}$$

where $B\left(L^{1/m}, \theta\right) = \sum_{j=0}^{j^{\max}} b(j,\theta)L^{j/m}$ is the exponential Almon lag with

$$b(j,\theta) = \frac{\exp\left(\theta_1 j + \theta_2 j^2\right)}{\sum_{j=0}^{j^{max}} \exp\left(\theta_1 j + \theta_2 j^2\right)}, \tag{25}$$

and with $\theta = (\theta_1, \theta_2)$. Here, $\hat{F}_{t_m}$ is a set of monthly factors estimated using one of the various approaches discussed in the previous section, $L^{j/m}X_t^{(m)} = X_{t-j/m}^{(m)}$, and $\hat{F}_{t_m}^{(3)}$ is skip sampled from the monthly factor, $\hat{F}_{t_m}$. That is, every third observation starting from the final one is

included in the predictor, $\hat{F}^{(3)}_{t_m}$. Since (25) includes lagged terms, all monthly factors are in the set of predictors. In this equation, the $L^{j/m}$ operator produces the value of X_{t_m} lagged by j/m periods. The above equation is a projection of quarterly $y_{t_q+h_q}$ onto monthly data, X_{t_m}, using up to $j^{\max}$ monthly lags. If we apply our real-time dataset structure in this framework, the basic MIDAS model in (24) is:

$$ {}_{t_m}Y_{t_q-k+h_q} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right) {}_{t_m}F^{(3)}_{t_m} + \varepsilon_{t_q}, \tag{26} $$

and assuming that there are r factors, $F_{t_m,1}, F_{t_m,2}, ..., F_{t_m,r}$, yields:

$$ {}_{t_m}Y_{t_q-k+h_q} = \beta_0 + \sum_{i=1}^{r} \beta_{1,i} B_i\left(L^{1/m}, \theta_i\right) {}_{t_m}F^{(3)}_{t_m,i} + \varepsilon_{t_q-k+h_q}. \tag{27} $$

Since we do not consider monthly real-time series and we interpolate missing values at the end of series in our monthly indicators, F_{t_m} always exists at time t_m. If we are in the first month of the quarter and the dependent variable (GDP) from previous quarter is not available, we 'pastcast' the previous quarter's value, 'nowcast' the current quarter, and 'forecast' future quarters. For example, the pastcast of Y_{t_q-1} at time t_m, where t_m is the first month of the quarter is:

$$ {}_{t_m}Y_{t_q-1} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right) {}_{t_m}F^{(3)}_{t_m-1} + {}_{t_m}\varepsilon_{t_q-1} \tag{28} $$

Note that $t_q - 1$ denotes one quarter ago and $t_m - 1$ does one month ago. The nowcast of Y_{t_q} at time t_m, where t_m is the first month of the quarter is:

$$ {}_{t_m}Y_{t_q} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right) {}_{t_m}F^{(3)}_{t_m} + {}_{t_m}\varepsilon_{t_q}, \tag{29} $$

and for the second month of the quarter, the nowcast of (29) is:

$$ {}_{t_m+1}Y_{t_q} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right) {}_{t_m+1}F^{(3)}_{t_m+1} + {}_{t_m+1}\varepsilon_{t_q}. \tag{30} $$

Finally, define the forecast h_q-ahead at time t_m as follows:

$$ {}_{t_m}Y_{t_q+h_q} = \beta_0 + \beta_1 B\left(L^{1/m}, \theta\right) {}_{t_m}F^{(3)}_{t_m} + {}_{t_m}\varepsilon_{t_q+h_q}. \tag{31} $$

According to Ghysels et al. (2004) and Andreou et al. (2010), given θ_1 and θ_2, the exponential lag function, $B(L^{1/m}, \theta)$, provides a parsimonious estimate that can proxy for monthly lags of the factors, as long as j is sufficiently large. It remains how to estimate θ and β. Marcellino

and Schumacher (2010) suggest using nonlinear least squares (NLS), yielding coefficients, $\hat{\theta}$ and $\hat{\beta}$. Clements and Galvao (2008) extend MIDAS by adding autoregressive (AR) terms, as follows:

$$ {}_{t_m}Y_{t_q-k+h_q} = \beta_0 + \eth Y_{t_q-k} + \sum_{i=1}^{r} \beta_{1,i} B_i \left(L^{1/m}, \theta_i\right) {}_{t_m}F^{(3)}_{t_m,i} + \varepsilon_{t_q-k+h_q}. \tag{32} $$

This approach enable us to treat serial correlation in the idiosyncratic components. In this paper, the coefficient for AR term(s), τ is estimated with the other coefficients using NLS.

5.2 Other MIDAS specifications

Marcellino and Schumacher (2010) use two different MIDAS specifications, smoothed MIDAS, which is a restricted form of basic MIDAS with different weights on monthly indicators, and unrestricted MIDAS, which relaxes restrictions on the lag polynomial used. These MIDAS models are explained in the context of the models we implement, as given in equations (29) and (32).

Smoothed MIDAS

Altissimo et al. (2010) propose a new Eurocoin Index, an indicator of economic activity in real-time. The index is based on a method to obtain a smoothed stationary time series from a large data set. Their index and methodology builds on that discussed in Marcellino and Schumacher (2010), and is used to nowcast and forecast German GDP. In particular, their model can be written as:

$$ {}_{t_m}Y_{t_q-k+h_q} = \hat{\mu}_Y + \mathbf{G}\hat{F}_{t_m} \tag{33} $$

$$ \mathbf{G} = \tilde{\Sigma}_{Y,F}\left(h_m\right) \times \hat{\Sigma}_F^{-1} \tag{34} $$

where $\hat{\mu}_Y$ is the sample mean of GDP, assuming that the factors are standardized, and $\mathbf{G}$ is a projection coefficient matrix. Here, $\hat{\Sigma}_F$ is the estimated sample covariance of the factors, and $\tilde{\Sigma}_{Y,F}\left(j\right)$ is a particular cross-covariance with j monthly lags between GDP and the factors, defined as follows:

$$ \tilde{\sum}_{Y,F}(j) = \frac{1}{t^* - 1} \sum_{m=M+1}^{t_m} {}_m Y_{t_q} \hat{F}^{(3)'}_{m-j}, \tag{35} $$

where $t^* = \text{floor}\left[\left(t_m - \left(M+1\right)/3\right)\right]$ is the number of observations available to compute the cross covariance, for $j = -M, ..., M$; and $M \geq 3h_q = h_m$, under the assumption that both GDP and the factors are demeaned. Note that $h_m = 3 \cdot h_q$. Complete computational details

are given in Altissimo et al. (2010) and Marcellino and Schumacher (2010). This so-called 'smoothed MIDAS' is a restricted form of basic the MIDAS model given in (24), with a different lag form.

Unrestricted MIDAS

Another alternative version of MIDAS involves using an unrestricted lag polynomial when weighting the explanatory variables (i.e. the factors). Namely, let:

$$ {}_{t_m}Y_{t_q-k+h_q} = \beta_0 + \mathbf{C}\left(L_m\right)\hat{F}^{(3)}_{t_m} + \varepsilon_{t_q-k+h_q}, \tag{36} $$

where $\mathbf{C}\left(L_m\right) = \sum_{j=0}^{j^{max}} \mathbf{C}_j L_m^j$ is an unrestricted lag polynomial of order j. Koenig et al. (2003) propose a similar model in the context of forecasting with real-time data, but not with factors. Marcellino and Schumacher (2010) provide a theoretical justification for this model and derive MIDAS as an approximation to a forecast equation from a high-frequency factor model in the presence of mixed sampling frequencies. Here, $\mathbf{C}\left(L_m\right)$ and β_0 are estimated by LS. Lag order specification in our forecasting experiments is done in two different ways. When using a fixed scheme where $j = 0$, automatic lag length selection is carried out using the SIC. Alternatively, if $k = 0$, our model only uses t_m dated factors in forecasting.

6 Empirical Results

6.1 Forecasting experiments

In addition to the MIDAS type models discussed above, we specify and estimate a number of benchmark models, against which the MIDAS framework is compared, when forecasting real-time GDP. The followings list summarizes the models compared in our experiments.

- *Autoregressive Model:* We nowcast or forecast GDP growth rates, ${}_{t_m}\hat{Y}_{t_q+h_q-k}$, h_q-steps ahead, using autoregressions with p lags, where p is selected using the SIC. Note that our AR model does not use monthly indicators; but since lagged GDP, as well as revised GDP data are available at various dates throughout the quarter, we still update our predictions monthly. The models is:

$$ {}_{t_m}\widehat{Y}_{t_q+h_q-k} = \hat{\beta}_0 + \hat{\beta}_1 \cdot {}_{t_m}Y_{t_q-k-1} + \ldots + \hat{\beta}_p \cdot {}_{t_m}Y_{t_q-k-p} \tag{37} $$

- *Random Walk Model:* We implement a standard random walk model, so that the growth

rate is assumed to be constant, although this constant value is re-estimated recursively, at each point in time.

- *Combined Bivariate Autoregressive Distributed Lag (CBADL) Model:* We use the so-called bridge equation, since it is widely used to forecast quarterly GDP using monthly data (see, e.g. Baffigi et al. (2004) and Barhoumi et al. (2008)), particularly at central banks. The CBADL model, which is a standard bridge equation, uses monthly indicators as regressors to predict GDP. It is composed of three steps, as given below. These three steps consist of:

  Step 1 - Construct forecasts of all N monthly explanatory variables, where m and q are selected using the SIC. Namely, specify and estimate: $X_{i,t_m} = \rho_1 X_{i,t_m-1} + \cdots \rho_m X_{i,t_m-m} + \zeta_{i,s}$

  Step 2 - Use lagged values of GDP as well as predictions of each individual monthly explanatory variables, order to obtain N alternative quarterly forecasts of GDP. Namely, specify and estimate:

  $${}_{t_m}Y_{i,t_q-k+h_q} = \mu_Y + \gamma_1 Y_{t_q-k-1} + \cdots + \gamma_{q_y} Y_{t_q-k-q_y} + \beta_{i,0}\widehat{X}_{i,t} + \cdots + \beta_{i,q_x}\widehat{X}_{i,t-q_x} + \upsilon_{i,t_q-k+h_q}$$

  Step 3 - Construct a weighted average of the above predictions. Namely:

  $${}_{t_m}\hat{Y}^{CBADL}_{t_q-k+h_q} = \frac{1}{N}\sum_{i=1}^{N} {}_{t_m}\hat{Y}_{i,t_q-k+h_q} \ ,$$

  where N is the dimension of explanatory variables, and in all models, m and q are selected using the SIC. Stock and Watson (2012) and Kim and Swanson (2014b) implement a version of this model.

As is the case with all of our models, the real-time feature of our experiments is carefully retained when specifying and estimating these models.

- *Bridge Equation with Exogenous Variables (BEX) :* This method is identical to CBADL model except that Step 2 is replaced with:

$$ {}_{t_m}Y_{i,t_q-k+h_q} = \mu_Y + \beta_{i,0}\widehat{X}_{i,t} + \cdots + \beta_{i,q_x}\widehat{X}_{i,t-q_x} + \upsilon_{i,t_q-k+h_q} \tag{38}$$

In all experiments, prediction model estimation is carried out using both recursive and rolling data windows, with the rolling window length set equal to 8 years (i.e., 32 periods of quarterly GDP and 96 monthly observations). Additionally, all recursive estimations begin with 8 years of data, with windows increasing in length prior to the construction of each new real-time forecast. Out-of-sample forecast performance is evaluated using predictions dating

beginning in 2000:Q1 and ending in 2013:Q4. Moreover, for each quarter, three monthly predictions are made. Figure 4 depicts the monthly/quarterly structure of our prediction experiments.

[Insert Figure 4 here]

Table 1 summarizes the forecast models and estimation methods used. In this table, AR, CBADL, and BEX denotes the benchmark models which do not use any factors, and are our alternatives to MIDAS regressions. The two interpolation methods discussed above (i.e., AR and VA interpolation) for addressing the ragged-edge problem are used when estimating factors via implementation of OPCA and RPCA. In addition, the EM algorithm and Kalman Filtering (KF) are used to estimate factors, without interpolation. Once factors are estimated, they are plugged into five different varieties of MIDAS regression model, including: Basic MIDAS w/o AR terms, Basic MIDAS w/ AR terms, Smooth MIDAS, and Unrestricted MIDAS w/o AR terms, and Unrestricted MIDAS w/ AR terms.

[Insert Table 1 here]

In order to assess predictive performance, we construct the mean square forecast error (MSFE) for all models. In conventional datasets that do not contain real-time data, MSFE criteria can be constructing by simply comparing forecasts with actual values of GDP. In the current context, we have to take a stand concerning what 'constitutes' actual values of GDP (i.e., which vintage is the actual data). We set our actual GDP growth, against which forecasts are compared, to be ${}_{t_m}Y^{(3)}_{t_q-k}$. However, we also evaluate the performance of our models using fully revised data. Other than definitional changes, Korean GDP is fully revised after 2 years, which corresponds to the 5th vintage; and so we also compare forecasts with actual data defined as ${}_{t_m}Y^{(5)}_{t_q-k}$. In general, the MSFE of the $i-$th model for h_q-step ahead forecasts is defined as follows:

$$MSFE^{(j)}_{i,h_q} = \sum_{t=R-h_q+2}^{T_q-h_q+1} \left({}_{t_m+3(h_q-k)+s}Y^{(j)}_{t_q-k+h_q} - {}_{t_m}\hat{Y}_{i,t_q-k+h_q} \right)^2, \quad j = 1, ..., 5 \qquad (39)$$

where R is the in-sample period, T_q is the total number of observations in quarter, ${}_{t_m+3(h_q-k)+s}Y^{(j)}_{t_q-k+h_q}$ is the observed value of the GDP growth rate, for $t_q - k + h_q$ when it is available, so that s denotes the smallest integer value needed in order to ensure availability of actual GDP growth rate data, $Y^{(j)}_{t_q-k+h_q}$ in real-time, and ${}_{t_m}\hat{Y}_{i,t_q-k+h_q}$ is the predicted value at $t_q - k + h_q$, for the

$i-$th model. For example, we forecast the GDP growth rate in 2015:Q1 at 2014:04, called ${}_{2014:04}\hat{Y}_{2015:Q1}$, and the first calendar date at which time we can observe data for 2015:Q1 is May 2015, i.e. ${}_{2015:05}\hat{Y}^{(1)}_{2015:Q1}$. As discussed above, we evaluate model performance using first available, and final data. In practice, we equate this procedure with using first available and 'most recently available' actual data; and associated MSFE statistics are denoted, $MSFE^{(1)}_{i,h_q}$ and $MSFE^{(last)}_{i,h_q}$,respectively.

Our benchmark model for carrying out statistical inference using MSFEs is the autoregressive model, and said inference is conducted using Diebold and Mariano (1995) (hereafter, the DM test). The null hypothesis of the DM test is that two models perform equally, when comparing squared prediction loss. Namely, we test:

$$H_0 : E\left[l\left(\varepsilon^1_{t+h|t}\right)\right] - E\left[l\left(\varepsilon^i_{t+h|t}\right)\right] = 0, \tag{40}$$

where $\varepsilon^1_{t+h|t}$ is the prediction error associated with the benchmark autoregressive model $\varepsilon^i_{t+h|t}$ is the prediction error of the $i-$th model, and $l(\cdot)$ is the quadratic loss function. If a DM statistic under the null hypothesis is negative and significantly different from zero, then we have evidence that model i outperforms the benchmark model (i.e., model 1). The DM statistic is:

$$DM = \frac{1}{P}\sum_{i=1}^{P}\frac{d_t}{\hat{\sigma}_{\bar{d}}} \tag{41}$$

where $d_t = \left(\widehat{\varepsilon^1_{t+h|t}}\right)^2 - \left(\widehat{\varepsilon^2_{t+h|t}}\right)^2$, $\bar{d}$ is the mean of d_t, $\hat{\sigma}_{\bar{d}}$ is a heteroskedasticity and autocorrelation robust estimator of the standard deviation of $\bar{d}$, and $\widehat{\varepsilon^1_{t+h|t}}$ and $\widehat{\varepsilon^2_{t+h|t}}$ are the estimated prediction errors corresponding to $\varepsilon^1_{t+h|t}$ and $\varepsilon^2_{t+h|t}$, respectively. In the sequel, our alternative models are the various MIDAS models.

6.2 Findings

There are a number of methodological as well as empirical conclusions that emerge upon examination of the results from our forecasting experiments. Prior to listing these findings, however, it is useful to recall the structure of our experiments. In particular, recall that we construct pastcast, nowcast, and forecast type predictions. Each of these are truly real-time, and they differ only in the timing of the predictions, relative to currently available data. To be specific, recall that in following our above notational setup, we construct three types of MSFEs. Consider construction of MSFEs using 'first available' data as the 'actual data'

against which predictions are compared.[1]

The pastcast prediction error of 2009:Q4 of 2010:M1 is defined as,

$$\varepsilon = {}_{2010:02}Y_{2009:Q4}^{(FirstAvailable)} - {}_{2010:01}\hat{Y}_{2009:Q4}, \tag{42}$$

where $\hat{Y}$. denotes the prediction. In this formulation, the first available value for calendar date 2009:Q4 is released in 2010:02, and hence the use of these dates in ${}_{2010:02}Y_{2009:Q4}^{(FirstAvailable)}$. The MSFE, called $MSFE_{-1}^{FirstAvailable}$ is the sum of squared ε, across the out-of-sample prediction period. Note that the subscript "-1" is used to denote pastcasts, when reporting MSFEs. The pastcast involves forecasting the 'past' value of GDP growth. Since there is a release lag in the GDP announcement, we may not know the value of GDP even once the quarter has ended, and hence the need for a pastcast. Note also that these "pastcasts" are made only once every three months (i.e., during the first month of each quarter, prior to the first release of previous quarter GDP growth data).

The nowcast for 2010:01 is the prediction for 2010:Q1 that is made during the first month of Q1 using:

$$\varepsilon = {}_{2010:05}Y_{2010:Q1}^{(FirstAvailable)} - {}_{2010:01}\hat{Y}_{2010:Q1}$$

The MSFE in this case is called $MSFE_{1}^{FirstAvailable}$. In same way, the MSFE for next quarter prediction is denoted by $MSFE_{4}^{FirstAvailable}$, where in this case

$$\varepsilon = {}_{2010:08}Y_{2010:Q2}^{(FirstAvailable)} - {}_{2010:01}\hat{Y}_{2010:Q2}. \tag{43}$$

Note that using predictions from the first month of each quarter, only $MSFE_{-1}^{FirstAvailable}$, $MSFE_{1}^{FirstAvailable}$, $MSFE_{4}^{FirstAvailable}$, and $MSFE_{7}^{FirstAvailable}$ are constructed, where $MSFE_{7}^{FirstAvailable}$ denotes the MSFE based on two quarter ahead predictions.

During the next month, i.e., 2010:02, we do not construct a pastcast because the first release GDP growth datum for 2009:Q4 is published by the statistical reporting agency at that time. Therefore, $MSFE_{-1}^{FirstAvailable}$ is not defined during the 2nd month of a quarter. However, we do have a new nowcast; namely ${}_{2010:02}\hat{Y}_{2010:Q1}^{(FirstAvailable)}$, which is the prediction for 2010:Q1 that is made during the second month of Q1. This allows use to form a new nowcast MSFE that is based on predictions that are 'closer' in calendar time to the actual release date of the historical data, using

$$\varepsilon = {}_{2010:05}Y_{2010:Q1}^{(FirstAvailable)} - {}_{2010:02}\hat{Y}_{2010:Q1}, \tag{44}$$

[1]We also use 'most recent' data as our actual data, when constructing MSFEs. This approach is probably the most consistent with actual practice at central banks, for example.

where the MSFE in this case is called $MSFE_2^{FirstAvailable}$. $MSFE_5^{FirstAvailable}$ and $MSFE_8^{FirstAvailable}$ are analogously constructed using

$$\varepsilon = {}_{2010:08}Y_{2010:Q2}^{(FirstAvailable)} - {}_{2010:02}\hat{Y}_{2010:Q2} \tag{45}$$

and

$$\varepsilon = {}_{2010:11}Y_{2010:Q3}^{(FirstAvailable)} - {}_{2010:02}\hat{Y}_{2010:Q3}, \tag{46}$$

respectively.

Finally, we have a third nowcast, made in the third month of the quarter, as well as additional forecasts, allowing us to analogously construct $MSFE_3^{FirstAvailable}$, $MSFE_6^{FirstAvailable}$, and $MSFE_9^{FirstAvailable}$.

Before turning to a discussion of our MSFE based examination of Korean real-time forecasting models, we summarize three methodological findings that are potentially useful for applied practitioners.

First, recall that the ragged-edge data problem can be addressed in a number of ways. One involves use of either AR or VA interpolation of missing data. Another involves directly accounting for this data problem via the use of the EM algorithm or Kalman filtering. Table 2 summarizes the results of a small experiment designed to compare AR and VA interpolation (EM and Kalman filtering methods are discussed later). In this experiment, both AR and VA interpolation are used to construct missing data, and all forecasting models are implemented in order to construct predictions, including MIDAS models, as well as benchmark models. Indeed, the only models not included in this experiment are MIDAS variants based on use of the EM algorithm and Kalman filtering. Entries in the table denote the proportion of forecasting models for which VA interpolation yields lower MSFEs than AR interpolation. Interestingly, proportions are always less than 0.5, regardless of whether pastcasts, nowcasts, or forecasts are compared, and whether 'first available' or 'most recent' data are used as our 'actual data'. Indeed, in most cases, only approximately 10% of models or less 'prefer' VA interpolation. This is taken as strong evidence in favor of using AR interpolation, and, thus, the remainder of results presented only interpolate data using the AR method. Complete results using both varieties of interpolation are available upon request from the authors.

[Insert Table 2 here]

Second, we compare forecasting performance by estimation type in an experiment for which results are summarized in Table 3. In particular, we are cognizant of the fact that issues relating to structural breaks, model stability, and generic misspecification play an important

role on the choice of using either rolling or recursive data windows when constructing real-time forecasting models. In lieu of this fact, we estimated all of our models using both recursive and rolling data windows, and entries in the table report the proportion of models for which the recursive estimation strategy is 'MSFE-best'. In the Korean case it turns out the recursive estimation dominates in all but three horizons, regardless of which data are used as our 'actual data'. The fact that the only three instances where rolling windows are 'MSFE-best' are early horizon cases using 'first available' data suggests that only in this case is there sufficient instability to warrant use of said rolling windows. Coupled with the fact that recursively estimated models dominate at all horizons using 'most recent' actual data, we have evidence that early release Korean data might not condition effectively on all available information. This property can be further investigated via the use of so-called data rationality tests, which is left to future research.

[Insert Table 3 here]

Third, a crucial aspect of forecasting models that utilize diffusion indices is exactly how many factors to specify. Bai and Ng (2002) and many others provide statistics that can be used for selecting the number of factors. However, there is no guarantee that the use of any of the exact tests will yield the 'MSFE-best' forecasting model. In one recent experiment, Kim (2013) uses Bai and Ng (2002), and finds that five to six factors are selected for a large scale Korean dataset. In this paper (see Table 4), we directly examine how many factors are used in 'MSFE-best' forecasting models. In particular, entries in Table 4 denote the proportion of times that models with a given fixed number of factors are MSFE-best among all of our factor-MIDAS models, including those estimated using the EM algorithm, the Kalman filter, AR interpolation (with each of OPCA and RPCA), and those estimated both with and without autoregressive lags. It is very clear from inspection of the results that either 1 or 2 factors, at most, are needed when the prediction horizon in more than 1 quarter ahead. On the other hand, for horizons -1 to 3 (i.e. all pastcasts and nowcasts), the evidence is more mixed. While 1 or 2 factors are selected around 1/2 of the time, 5 or 6 factors are also selected around 1/2 of the time. Interestingly, there is little evidence that using an intermediate number of factors is useful. One should either specify a very parsimonious 1 or 2 factor models, or one should go with our maximum of 5 or 6. It is clear that forecast horizon matters; and this is consistent with the mixed evidence on this issue. Namely, some authors find that very few factors are useful, while others suggest using 5 or more. Both of these results are confirmed in our experiment, with forecast horizon being the critical determining characteristic. The overall conclusion, thus, appears to be that when uncertainty is more prevalent (i.e., longer

forecast horizons), then parsimony is the key ingredient to factor selection. This conclusion is not at all surprising, and is in accord with stylized facts concerning model specification when specifying linear models.

[Insert Table 4 here]

We now turn to our discussion to the evaluation of the forecasting models used in our experiment.

Entries in Tables 5, Panel (a) are MSFEs for all models, relative to the benchmark AR(SIC) model. Thus, entries greater than 1 imply that the corresponding model performs worse than the AR(SIC) model. The column headers in the table denote the forecast horizon, ranging from '-1' for pastcasts to 9 for two quarter ahead predictions. In this framework, horizons 1, 2, and 3 are monthly nowcasts for the current quarter, and subsequent horizons pertain to monthly forecasts made during the subsequent two quarters. Notice that the first three rows in the table correspond to our other standard models (i.e., the RW, CBADL and BEX models). The rest of the rows in the table report findings for our various MIDAS type models, constructed with 1, 2, and 6 factors. Recall that there are 5 different MIDAS specifications: 'Basic MIDAS with and without AR terms', 'Unrestricted MIDAS with and without AR terms', and 'Smoothed MIDAS'. Estimation is done recursively, the ragged-edge problem is solved by AR interpolation, four different factor estimation methods are reported on, including OPCA, RPCA, EM and KF, and 'actual' data are assumed to be 'first available' data, for the purpose of forecast evaluation and MSFE construction. Table 5, Panel (b) is the same as Panel (a), except that 'most recent' instead of 'first available' data are used when evaluating forecasts. Complete results pertaining to other permutations such as the use of alternative interpolation methods, estimation strategies, and numbers of factors are available upon request.

Digging a bit further into the layout of this table, note that, bold entries denote models that are 'MSFE-better' than the AR(SIC) model, entries with superscript 'FB' are 'MSFE-best' for a given forecast horizon and number of factors, and entries with the superscript 'GB' denote models that are 'MSFE-best' across all permutations, for a particular forecast horizon.

[Insert Table 5 here]

When evaluation is carried out with first available data (see Panel (a) of Table 5), it turns out that for pastcasting and nowcasting, factor-MIDAS models without AR terms as well as other benchmark models do not work well, regardless of the number of factors. In

these cases, AR(SIC) models dominate, in terms of MSFE. This suggests that for short forecast horizons, the persistence of GDP growth is strong, and well modeled using linear AR components. As the forecast horizon gets longer, models without AR terms benefit from substantial performance improvement of the other components of the models, such as MIDAS component. Indeed, in some cases, models without AR terms outperform models with AR terms at longer horizons. This is interesting, as it suggests that uncertainty in autoregressive parameters does not carry over as much to other model parameters, as the horizon increases, and the role for MIDAS thus increases in importance.

Evidently, upon inspection of MSFEs, there is little to choose between OPCA and RPCA estimation methods. Thus, given computing considerations [2], RPCA is preferred when analyzing large datasets. Among the other factor estimation methods, KF and EM algorithm perform well in longer forecast horizon, but KF is much better than EM for shorter horizons. Turning to the number of factors used in prediction model construction, it is noteworthy that 1 or 2 factors are strongly preferred for longer forecast horizons, in accord with our earlier findings. The exception to this finding is when Smoothed MIDAS is used, in which case 6 factors are always preferred, regardless of horizon. This finding, though, is mitigated somewhat by the finding that Smoothed MIDAS never yields 'MSFE-best' models that are 'globally best' (i.e., GB) for a given forecast horizon. Still, if one must use many factors, then Smoothed MIDAS does yield the 'MSFE-best' model at many horizons.

Panel (b) of Table 5 presents MSFEs constructed using 'most recent' data. In many practical settings, forecasters assess models using this variety of data. Interestingly, in this set of results, we immediately observe that the 'MSFE-best' model is almost never the AR(SIC). Moreover, our earlier finding that models without AR terms are not preferred to the AR(SIC) for pastcasting and nowcasting is reversed. Indeed, for these forecast horizons, the 'MSFE-best' models do not contain AR terms, and are factor-MIDAS models. This is interesting, as it suggests that the revision process itself negates the usefulness of autoregressive information, and model specification using other MIDAS and factor variables are better. This result points to the need to be very careful when specifying models, as the benchmark data against which predictions are compared is crucial to model selection. The rest of the findings in this table, however, mirror those from Panel (a) of the table.

In order to obtain a clearer picture of the rather startling findings concerning the inclusion (or not) of AR terms, we summarize the findings of Table 5 in a concise manner in Table 6. In particular, in Table 6 the 'GB' models (i.e., those that are 'MSFE-best' across all

[2]Computation when using RPCA is around 10% faster that when using OPCA, based on a run using an Intel i7-3700 processor with 16GB of RAM.

permutations, for a particular forecast horizon are given in the first row. The remainder of the table summarizes associated 'MSFE-best' models (and corresponding factor estimation schemes) for a given number of factors coupled with data type and forecast horizon. The results discussed above are made clear in this table. Namely, factor-MIDAS models are almost everywhere 'MSFE-best' with the exception of pastcasts and nowcasts. Additionally, models without AR terms are important when using 'most recent' data at shorter horizons, and when using 'first available' data at longer horizons. Finally, PCA factor estimation methods are almost always preferred, and smoothed MIDAS type models are only useful if including many factors when predicting at the longest horizons. Of course, we do not recommend this, as using many factors for long horizon forecasting has been shown to yield more imprecise predictions than when fewer factors are used.

[Insert Table 6 here]

Figure 5 plots MSFE values (not relative to the AR(SIC) model) for various prediction models. In the figure, 'Basic' and 'Unrestricted' denote factor-MIDAS models with two factors (refer to above discussion, and to Table 5 for further discussion of this terminology), and AR interpolation with OPCA estimation is used throughout. Panels (a) and (b) correspond to recursively estimated models using 'first available' (i.e., first-vintage) and 'most recent' (i.e., fully revised or last vintage) data, respectively. Panels (c) and (d) are same, but use rolling estimation. In this figure, $h = 0$ corresponds to pastcasts (called $h = -1$ in the tables), $h = 1, 2, 3$ correspond to nowcasts, and $h = 4, ..., 9$ correspond to forecasts. As discussed above, in conventional forecasting experiments, most forecasters use fully revised data for forecasting evaluation. With these data, factor-MIDAS dominates all other benchmark models, at all horizons, as seen in Panel (b); and RW and CBADL perform poorly at all horizons. Also, among the factor-MIDAS models, 'Basic' factor-MIDAS dominates. However, if we instead use the 'first available' data[3], factor-MIDAS models as well as BEX models dominate the AR(SIC), particularly at long forecast horizons (see Panel (a)). However, as the forecast horizon gets shorter (i.e., we move from forecast→ nowcast→pastcast), AR(SIC) and RW models perform better than other models, as confirmed in our discussion of the results presented in Table 5.

[Insert Figure 5 here]

[3]Following the definition given in Section 2, the first vintage data is ${}_{t_m}Y^{(1)}_{t_q} = \log {}_{t_m}Z^{(1)}_{t_q} - \log {}_{t_m}Z^{(3)}_{t_q-4}$ where ${}_{t_m}Z^{(1)}_{t_q}$ is a t_q quarter's GDP we can observe at time t_m , and ${}_{t_m}Z^{(3)}_{t_q-4}$ is a GDP one year behind. Superscript (3) denotes the third revised value. Conventionally, third revised one is usually a most recent data we can observe at time t_m and the growth rate is defined with it. Therefore, it should not be a third revised one.

With a rolling estimation scheme, the forecast performance of factor-MIDAS models and AR(SIC) models are similar for all horizons. However, we know from earlier discussion that recursively estimated models generally perform better, in our experiments. Still, it is worth stressing that finding do change when estimation schemes change.

In Figure 6, MSFE values are plotted for the same set of models as in Figure 5. However, in this figure, Panels (a)-(d) contain plots based on the use of different factor estimation methods when specifying the models (i.e., OPCA, RPCA, EM and KF), only first available data are used for MSFE construction, all models are specified with one factor, and AR interpolation is implemented. In light of this, Panel (a) in Figures 6 and 5 is the same. A number of conclusions emerge upon inspection of this figure. First, the pattern of increasing MSFE as forecast horizon increases is observed for all factor estimation methods (compare all 4 panels in the figure), as expected. Also, all estimation methods appear to be rather similar, when faced with 'first available' data. However, even though MSFEs are similar across factor estimation methods, the MSFE magnitudes are slightly higher based on the use of EM and KF, than when OPCA and RPCA are used for estimation. Interestingly, only our top two MIDAS models (that include AR terms) outperform the benchmark AR(SIC) model at all forecast horizons, as can be seen by inspection of the results in Table 5. Inspection of the plots in Figures 7 and 8, which are the same as Figure 6, except that 2 and 3 factors are specified, respectively, indicate that this finding continues to hold, as the number of factors increases. However, the overall ranking of the entire set of models does become more unclear, particularly with 6 factors. Indeed, in the 6 factor case, MSFE values for some of our non-MIDAS models are so high that the models are completely unreliable. This points to another concern when specifying so many factors, in addition to the issues discussed above when exploring the results in Table 5. Our other findings based on inspection of Figure 6 remain largely the same when the number of factors is increased to 2 and then 6.

[Insert Figure 6 here]
[Insert Figure 7 here]
[Insert Figure 8 here]

Figures 9 - 11 plot MSFEs of selected MIDAS specifications with $r = 1, 2$ and 6. In these figures, MIDAS results are presented with factors estimated using OPCA, RPCA, EM and KF. Additionally, various benchmark models are included (i.e., AR(SIC), RW, CBADL, and BEX). Using these figures, we can compare the performance of factor estimation methods for a given MIDAS model and value of r. When $r = 1$, RPCA or OPCA are clearly preferred.

However, when $r = 2$, Kalman filtering also works well at many forecast horizons.[4] Finally, as previously observed, when the number of factors is increased, forecast performance worsens substantially for 'Basic MIDAS' and 'Unrestricted MIDAS', as seen in Figure 11. Interestingly, 'Smoothed MIDAS' continues to perform well, even when $r = 6$. This points to the importance of smoothing when the number of factors is large.

7 Concluding Remarks

We introduce a real-time dataset for Korean GDP, and analyze the usefulness of the dataset for forecasting, using standard linear as well a large variety of factor type mixed frequency (MIDAS) models. In addition, various factor estimation schemes, data interpolation approaches, and data windowing methods are examined.

When comparing MSFEs, only approximately 10% of models perform best when using vertical alignment or VA interpolation, with 90% favoring autoregressive or AR interpolation. Models estimated using rolling data windows are only 'MSFE-best' at 3 forecast horizons, when using 'first available' data, and are never 'MSFE-best' when 'most recent' data are used. Given the common preference amongst empirical researchers to use 'most recent' data, it is clear that in the case of Korean GDP, recursive estimation is preferred, perhaps implying that any structural instability in our 'MSFE-best' models is mild. With regard to the number of factors to specify in prediction models, either 1 or 2 factors, at most, are needed when the prediction horizon in more than 3 months ahead. On the other hand, for horizons -1 to 3 (i.e. all pastcasts and nowcasts), the evidence is more mixed. While 1 or 2 factors are selected around 1/2 of the time, 5 or 6 factors are also selected around 1/2 of the time. Interestingly, there is little evidence that using an intermediate number of factors is useful. One should either specify a very parsimonious 1 or 2 factor models, or one should go with our maximum of 5 or 6. In summary, forecast horizon matters, in the sense that when uncertainty is more prevalent (i.e., longer forecast horizons), then parsimony is the key ingredient to factor selection, and any more than 1 or 2 factors leads to worsening predictive performance.

Turning to the findings of our prediction experiments, note that when evaluation is carried out with 'first available' data, for pastcasting and nowcasting, factor-MIDAS models without

[4]The MSFEs of models using OPCA are almost the same as those based on the use of RPCA, so that two graphs overlap to a large extent.

AR terms as well as other benchmark models do not work well, regardless of the number of factors. In these cases, pure autoregressive models dominate, in terms of MSFE. This suggests that for short forecast horizons, the persistence of Korean GDP growth is strong, and well modeled using linear AR components. Indeed, in many of these cases, our simplest linear AR models are 'MSFE-best'. As the forecast horizon gets longer, simple linear models are no longer 'MSFE-best', and models without AR terms in some cases outperform models with AR terms. This is interesting, as it suggests that uncertainty in autoregressive parameters does not carry over to other model parameters, as the horizon increases, and the role for MIDAS thus increases in importance. When 'most recent' real-time data are used in our prediction experiments, the reverse holds. Namely, more complicated MIDAS models dominate at all forecast horizons, and AR terms are only useful at longer forecast horizons. Given that 'most recent' data are those that are most often used by empirical researchers, we thus have direct evidence of the usefulness of factor-MIDAS coupled with real-time data for forecasting Korean GDP.

Table 1: Summary of Models and Estimation Methods*

Estimation Scheme	MIDAS	Factor Estimation	Interpolation
	Basic w/o AR term	OPCA	AR
	Basic w/ AR term		
		RPCA	VA
Recursive	Unrestricted w/o AR term	EM algorithm	
	Unrestricted w/ AR term		
Rolling	Smoothed	Kalman Filtering	
	AR		
	CBADL		
	BEX		

Model	Description
AR(SIC)	Autoregressive model with length of lags determined by SIC
RW	Random Walk
CBADL	Combined Bivariate Autoregressive Distributed Lag model
BEX	Bridge Equation with Exogenous Variable
Basic w/o AR	Basic MIDAS model without AR terms
Basic w/ AR	Basic MIDAS model with AR terms
Unrestricted w/o AR	Unrestricted MIDAS model without AR terms
Unrestricted w/ AR	Unrestricted MIDAS model with AR terms
Smoothed	Smoothed MIDAS model

* Notes: Non-factor-MIDAS type models include AR(SIC), RW, CBADL and BEX. Three types of factor-MIDAS models are specified ('Basic', 'Unrestricted', and 'Smoothed'), and each of these are estimated using each factor estimation method (OPCA and RPCA), interpolation method (AR and VA), and factor-MIDAS estimation method (EM algorithm and Kalman filter). Finally, all of these permutations are implemented using each of recursive and rolling data windowing strategies. For complete details see Section 6.

Table 2: Comparison of Forecasting Performance with AR and VA Interpolation*

	Pastcast	Nowcast			Forecast					
	prev. qtr.	current quarter			1 quarter ahead			2 quarter ahead		
Horizon	-1	1	2	3	4	5	6	7	8	9
First available	0.285	0.337	0.110	0.145	0.151	0.134	0.105	0.134	0.093	0.186
Most Recent	0.058	0.093	0.110	0.058	0.180	0.157	0.209	0.337	0.262	0.326

* Notes: See notes to Table 1. Forecasting performance is evaluated by comparing MSFEs across all of models which use interpolated missing values, including CBADL, BEX and factor-MIDAS models with OPCA and RPCA. Entries in the table report the proportion of times that the MSFE of models with AR interpolation is greater than 'like' models with VA interpolation. MSFEs are calcluated by comparing predictions with both 'first available' and 'most recent' actual data (see Section 3 for a detailed description of our real-time dataset). Thus, entries less than 0.5 indicate that AR interpolation performs better than VA, on average, across all model permutations.

Table 3: Comparison of Forecasting Performance by Estimation Type*

	Pastcast	Nowcast			Forecast					
	prev. qtr.	current quarter			1 quarter ahead			2 quarter ahead		
Horizon	-1	1	2	3	4	5	6	7	8	9
First available	0.747	0.782	0.653	0.465	0.400	0.147	0.059	0.018	0.029	0.082
Most Recent	0.218	0.194	0.171	0.235	0.282	0.218	0.329	0.353	0.300	0.459

* Notes: See notes to Table 2. Forecasting performance is evaluated by comparing MSFEs across all models, with MSFEs calculated by comparing predictions with both 'first available' and 'most recent' actual data, as in Table 2. However, in this table, entries report the proportion of times that the MSFEs of models estimated recursively are greater than when 'like' models are estimated using rolling data windows. Thus, entries less than 0.5 indicate that recursive estimation yields lower MSFEs, on average, across all model permutations.

Table 4: Comparison of Forecasting Performance Using Differing Numbers of Factors *

		Pastcast	Nowcast			Forecast					
		prev. qtr.	current quarter			1 quarter ahead			2 quarter ahead

* Notes: See notes to Table 3. The proportion of factor-MIDAS 'MSFE-best' models, when comparing 'like' models with the number of factors varying from 1 to 6 is reported in this table. This is done when MSFEs are calculated using either 'first available' or 'most recent' data, as well as for a number of pastcast, nowcast, and forecast horizons. See Section 6.2 for a detailed discussion of the different horizons reported on. Additionally, all results are based on OPCA and RPCA using AR interpolation, and we use only recursive estimation.

Table 5: Relative MSFEs When Pastcasting, Nowcasting, and Forecasting Korean GDP*

* Notes: See notes to Tables 1-4. Entries in this table are ratios of point MSFEs of the benchamrk AR(SIC) model and each other model, for various estimation methods and horizons. Panel (a) reports MSFEs calculated using 'first available' quarterly historical data when calculating prediction errors, and Panel (b) reports MSFEs calculated using 'most recent' quarterly historical data when calculating prediction errors. All results are based on recursively estimated models. The column denoted by 'Pastcast' contains MSFEs for quarterly forecasts of GDP made 1-month prior to the calendar date of the quarterly GDP. The columns denoted by 'Nowcast' contain MSFEs for forecasts of the first, second and third months of each quarterly calendar dated GDP observation. Finally, the columns denoted by 'Forecast' contain MSFEs based on predictions of months 4-6 ahead (for 1-quarter ahead predictions) and months 7-9 ahead (for 2-quarter ahead predictions). Bold entires denote cases for which the point MSFE of a given model is lower than the point MSFE of the AR(SIC) model. Entries superscripted by a * (5% level) and a ** (10% level) are significantly better than the AR(SIC) model, based on application of the Diebold-Mariano predictive accuracy test. Finally, entries subscripted with 'FB' denote the MSFE-best models for a given number of estimated factors and for each horizon, while entries subscripted with 'GB' denote MSFE-best models across all specification permutations, for a given horizon. See Table 6 for complete details.

Table 6: Summary of MSFE-Best Models Across All Modelling Permutations*

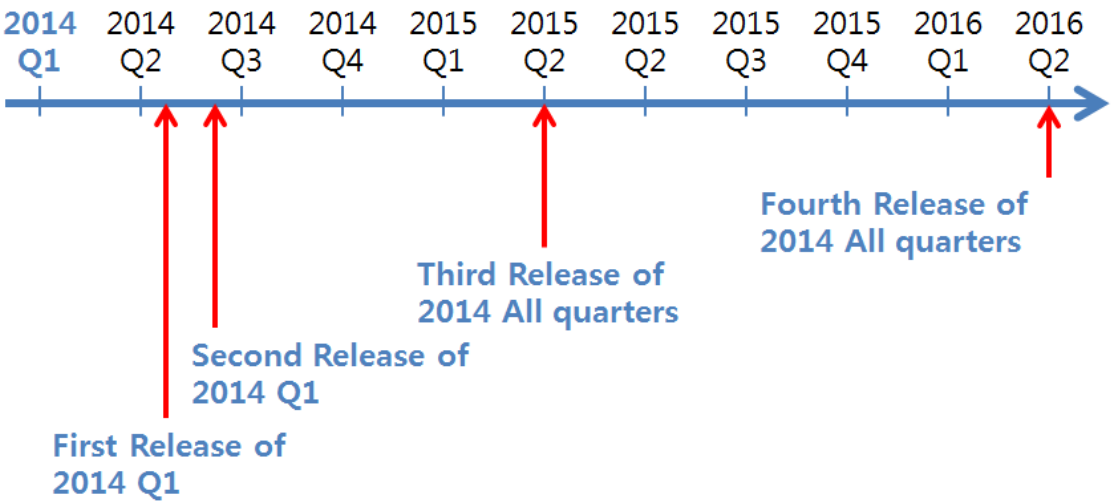
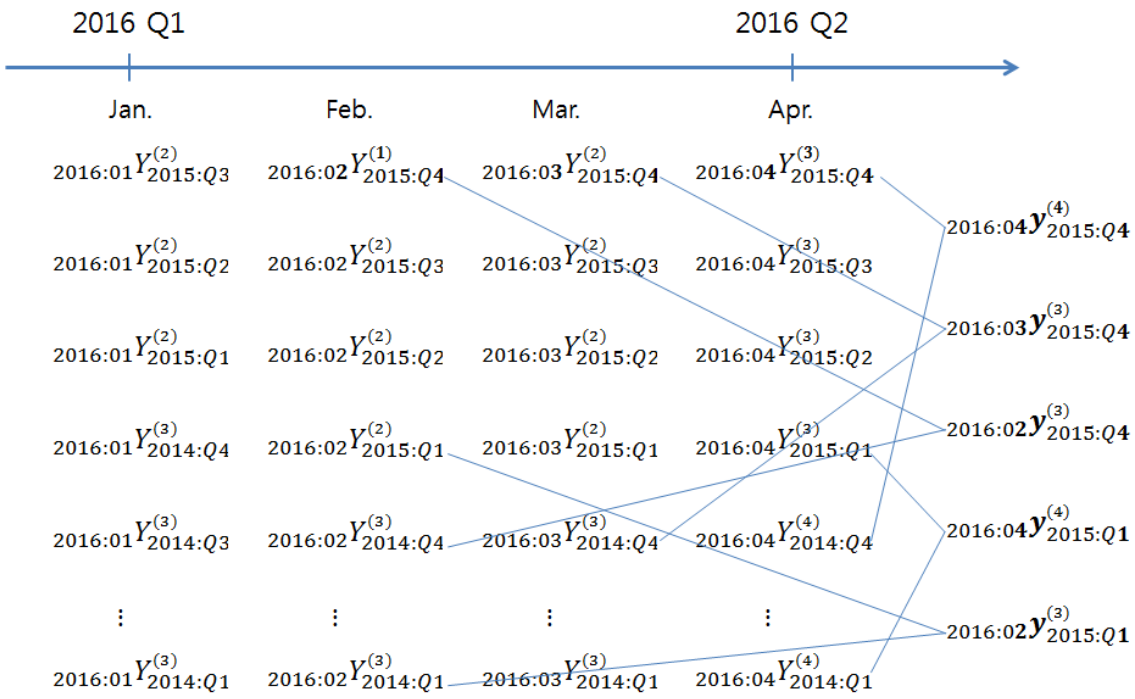
* Notes: See notes to Table 5. Entries indicate the model and estimation methods for all MSFE-best specifications, by historical data type, number of factors used, and horizon. Entries in the row labelled 'All' are the MSFE-best models across all factor specifications, for a given historical data type. All model estimation is done recursively and AR interpolation is used for missing value construction. For example, for the 'Pastcast' horizon, the 'Basic factor-MIDAS' model with AR terms and with factors estimated using OPCA is the 'globally best' performer when MSFEs are constructed using 'first available' historical data. When MSFEs based on the use of OPCA and RPCA are the same up to three decimal places, the PCA method is denoted by 'both PCA'.

Figure 1: Release Dates for Real-Time Korean GDP*



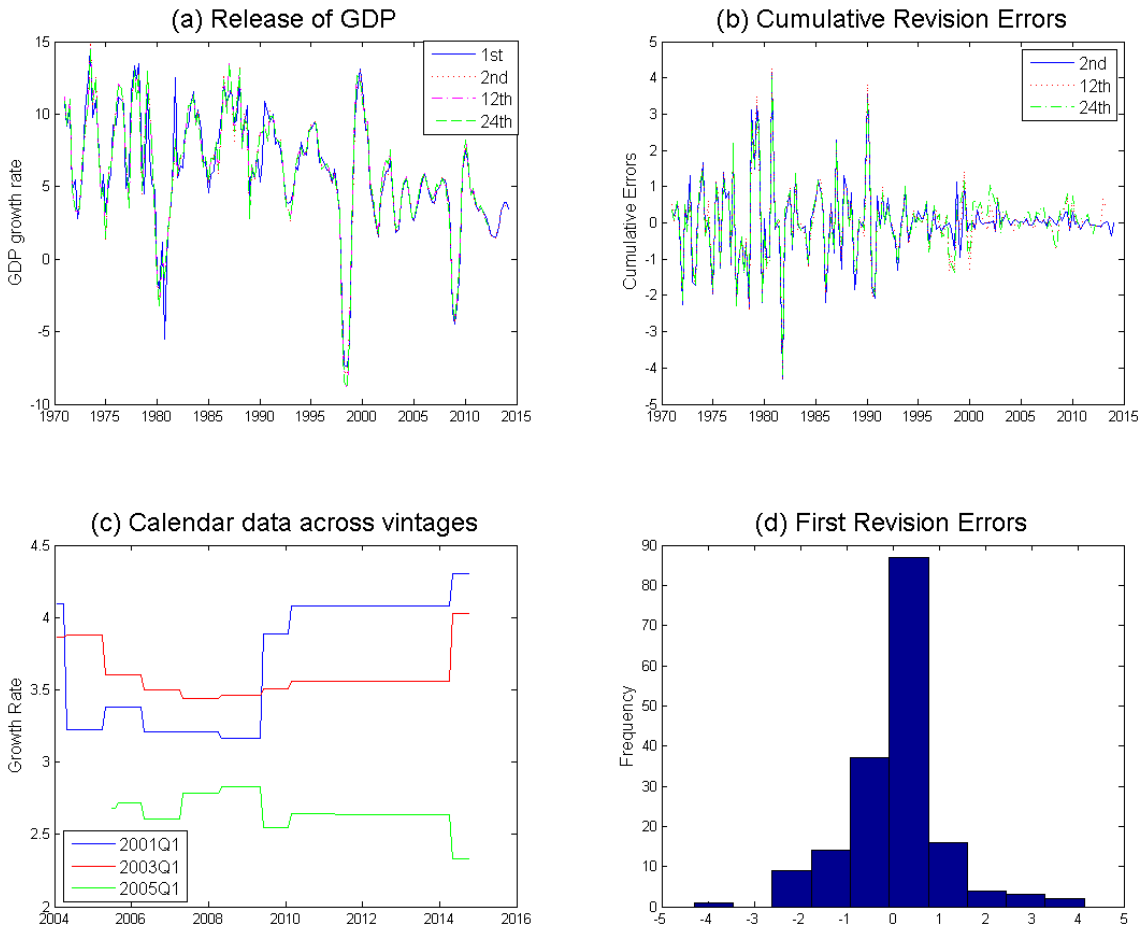
* Notes: See Sections 2 and 3 for complete details.

Figure 2: Depiction of Annualized GDP Growth Rates Based on Real-Time Data*



* Notes: See Section 2 for a detailed discussion of the dating conventions used in this diagram.

Figure 3: Historical Real-Time Data Releases for Korean GDP*



* Notes: In Figure (a), the solid line depicts 1st release GDP, the dotted line depicts 2nd rele, and the dot-dash line depicts final release data. Figure (b) depicts cummulative revision errors between the 1st and either the 2nd, 12th, or 24th releases. Figure (c) shows how the growth rate of 2001:1, 2003:1 and 2005:1 calendar dated GDP evolves as the series is revised. Figure (d) plots the distribution of first revision errors (i.e., the differences between 1st and 2nd data releases).

Figure 4: Structure of Monthy/Quarterly Prediction Experiments*

Month	Pastcast	Nowcast	Forecast		
2010:01	$_{2010:01}\hat{Y}_{2009:Q4}$	$_{2010:01}\hat{Y}_{2010:Q1}$	$_{2010:01}\hat{Y}_{2010:Q2}$	$_{2010:01}\hat{Y}_{2010:Q3}$	$_{2010:01}\hat{Y}_{2010:Q4}$

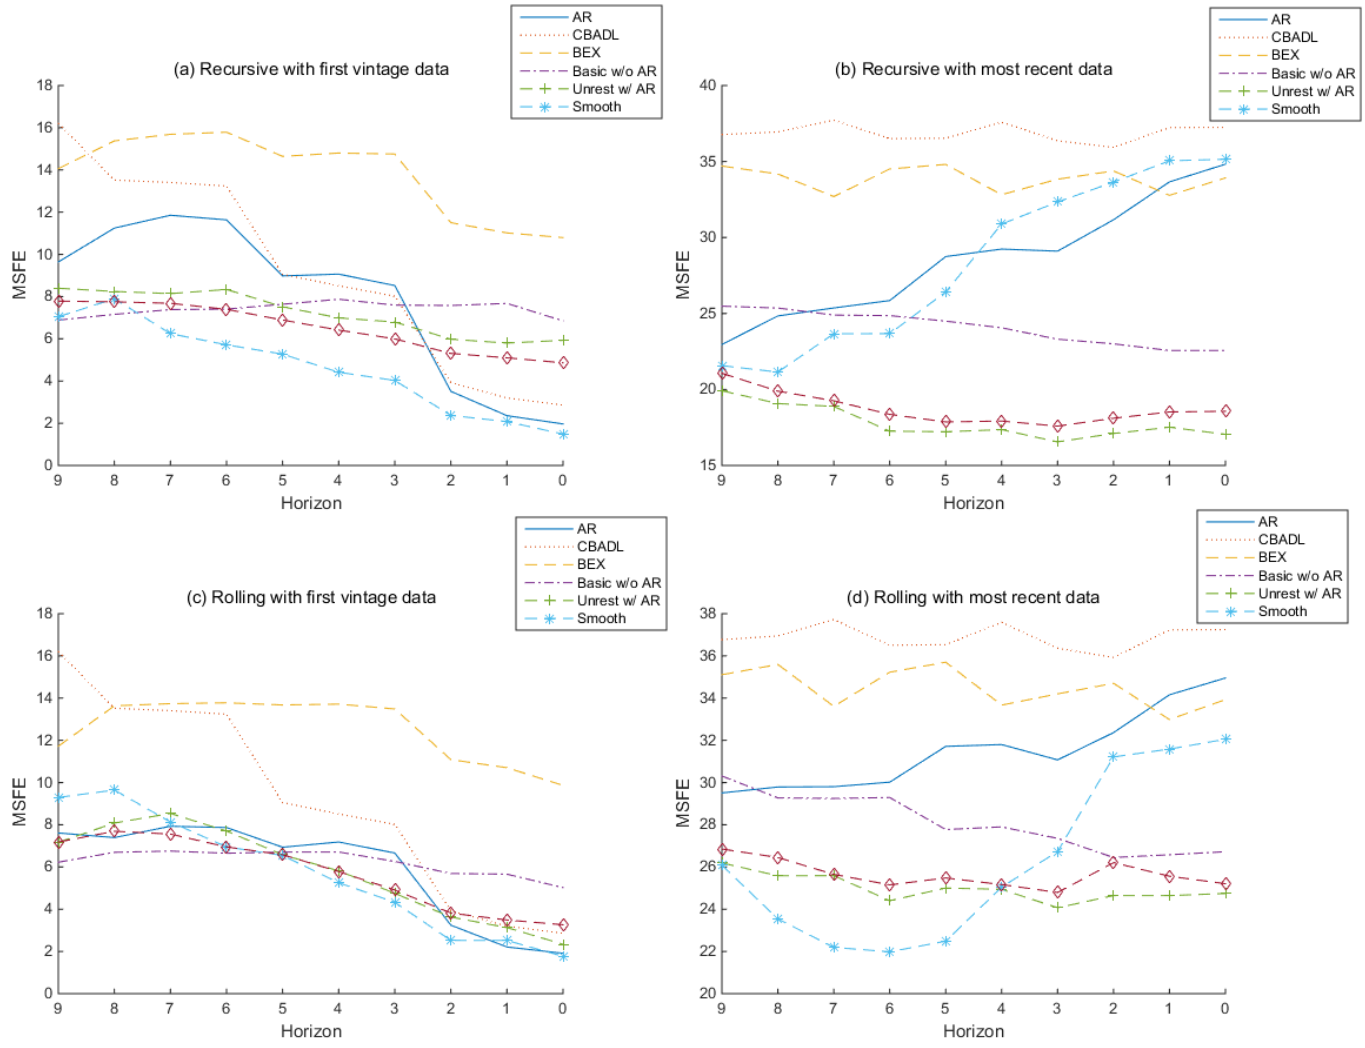
⋮	⋮	⋮	⋮	⋮	⋮

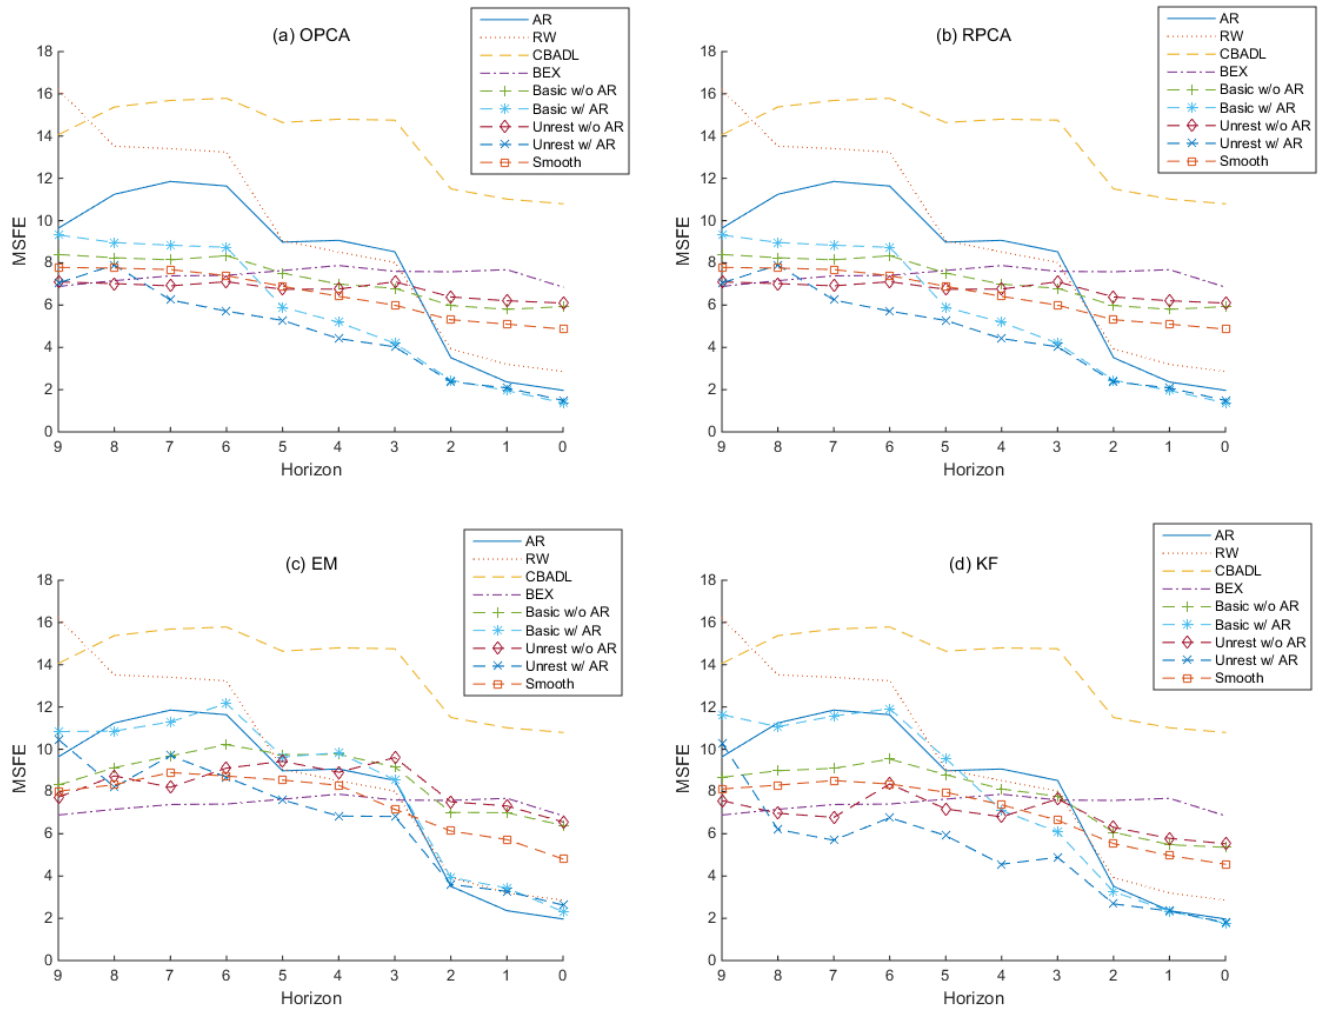
* Notes: This table describes the timing of monthly pastcasts, nowcasts and forecasts of quarterly GDP. For example, in 2010:01 we pastcast the GDP growth of 2009:Q4, since its value is not available yet in 2009:Q4; and we nowcast all three months in 2010:Q1. Finally, at the same point in time we also create monthly forecasts of GDP at 2010:Q2 and 2010:Q3. In the next month, 2010:02, we do not pastcast 2009:Q4 since its value is now available. For complete details, refer to Section 6.

Figure 5: Forecasting Using Real-time vs. Most Recent Data*



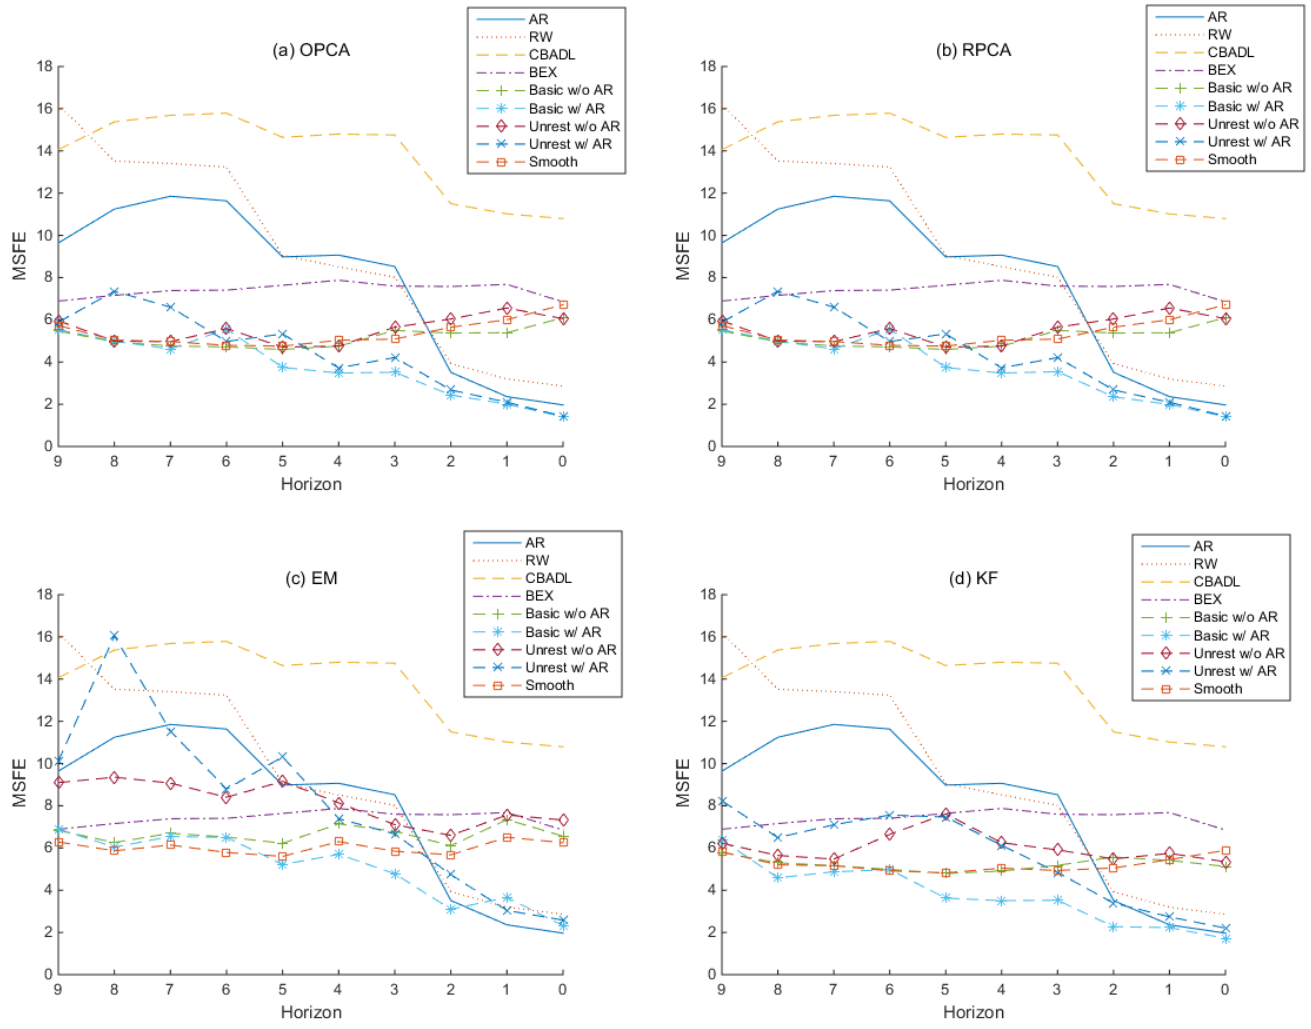
* Notes: This figure plots MSFEs for various models estimated using recursive and rolling data windows and constructed using either first vintages (i.e., ${}_{t_m}Y_{t_q}^{(1)}$) or 'most recent' data (i.e., fully revised data: ${}_{t_m}Y_{t_q}^{(Last)}$). Factor-MIDAS models are estimated using OPCA and AR interpolation, and horizons (depicted on the horizontal axes of the graphs) range from nine month ahead (forecasts) to zero months ahead (pastcasts). See Section 6 for further details.

Figure 6: MSFEs of Forecasting Models Constructed Using One Factor ($r = 1$)*



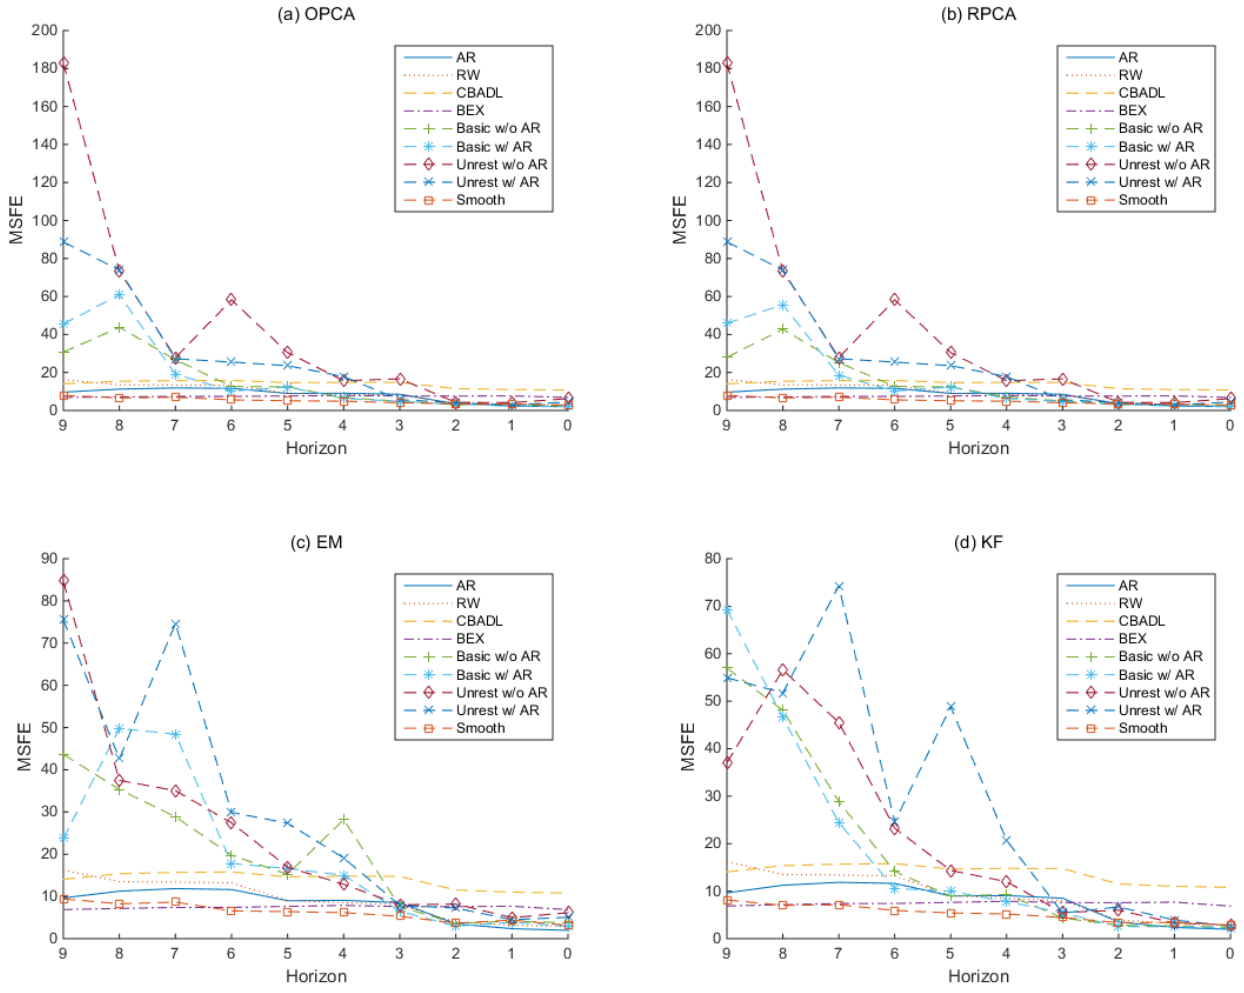
* Notes: See notes to Figure 5. Each of panel plots MSFEs for various models for a different estimation method. Benchmark models, including AR, CBADL and BEX, are redundantly included in all panels for comparability across panels. 'Basic w/o AR' and 'Basic w/ AR' are the basic factor-MIDAS models with and without AR terms. 'Unrest' and 'Smooth' denote alternative factor-MIDAS specifications (see Section 5). OPCA and RPCA are implemented with AR interpolation, and all forecasts are based on recursively estimated models. See Section 6 for complete details.

Figure 7: MSFEs of Forecasting Models Constructed Using Two Factors ($r = 2$)*



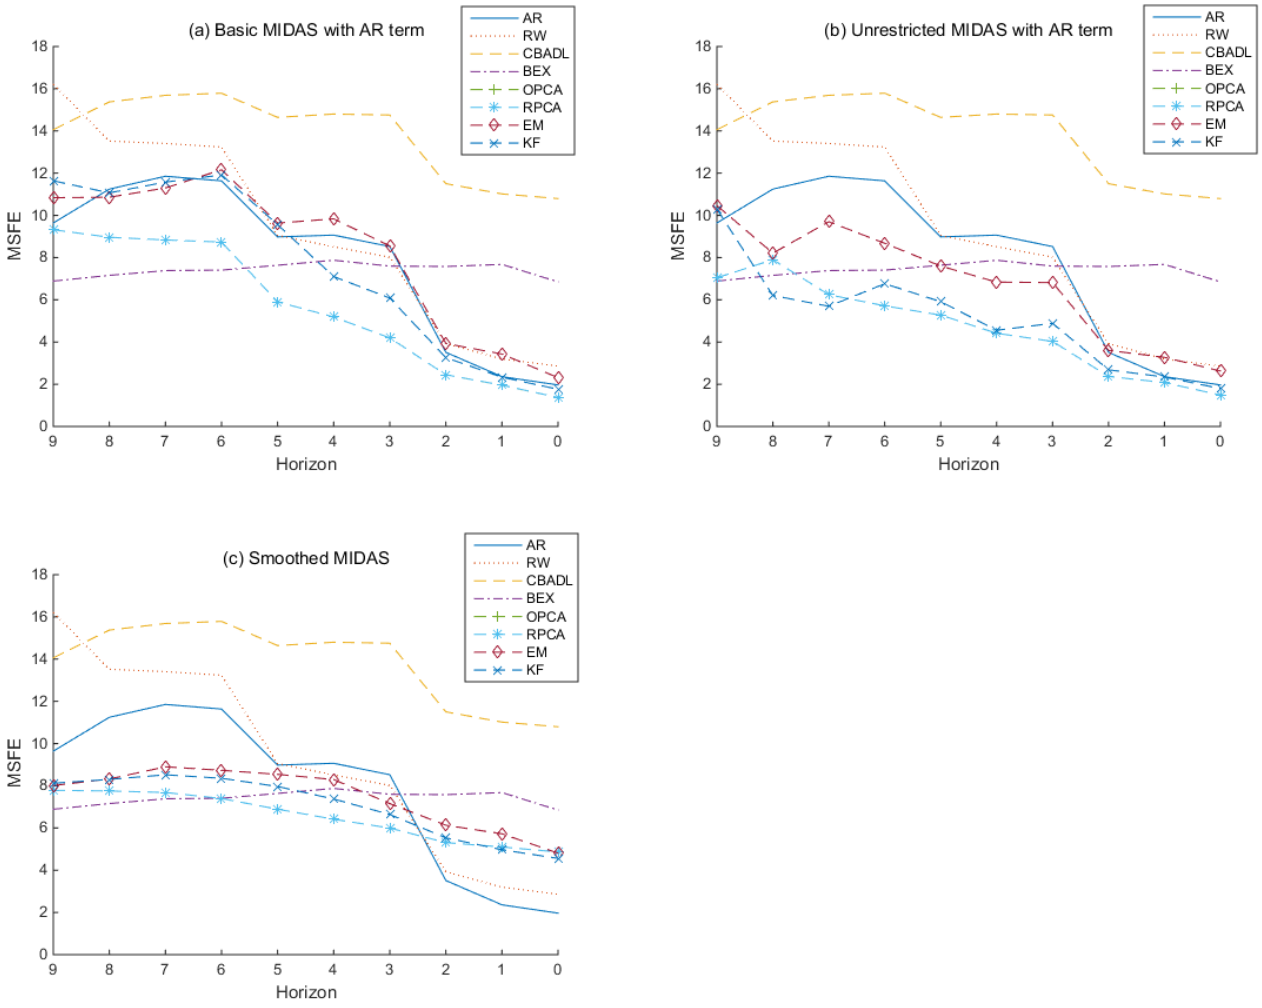
* Notes: See the Notes to Figure 6.

Figure 8: MSFEs of Forecasting Models Constructed Using Six Factors ($r = 6$)*



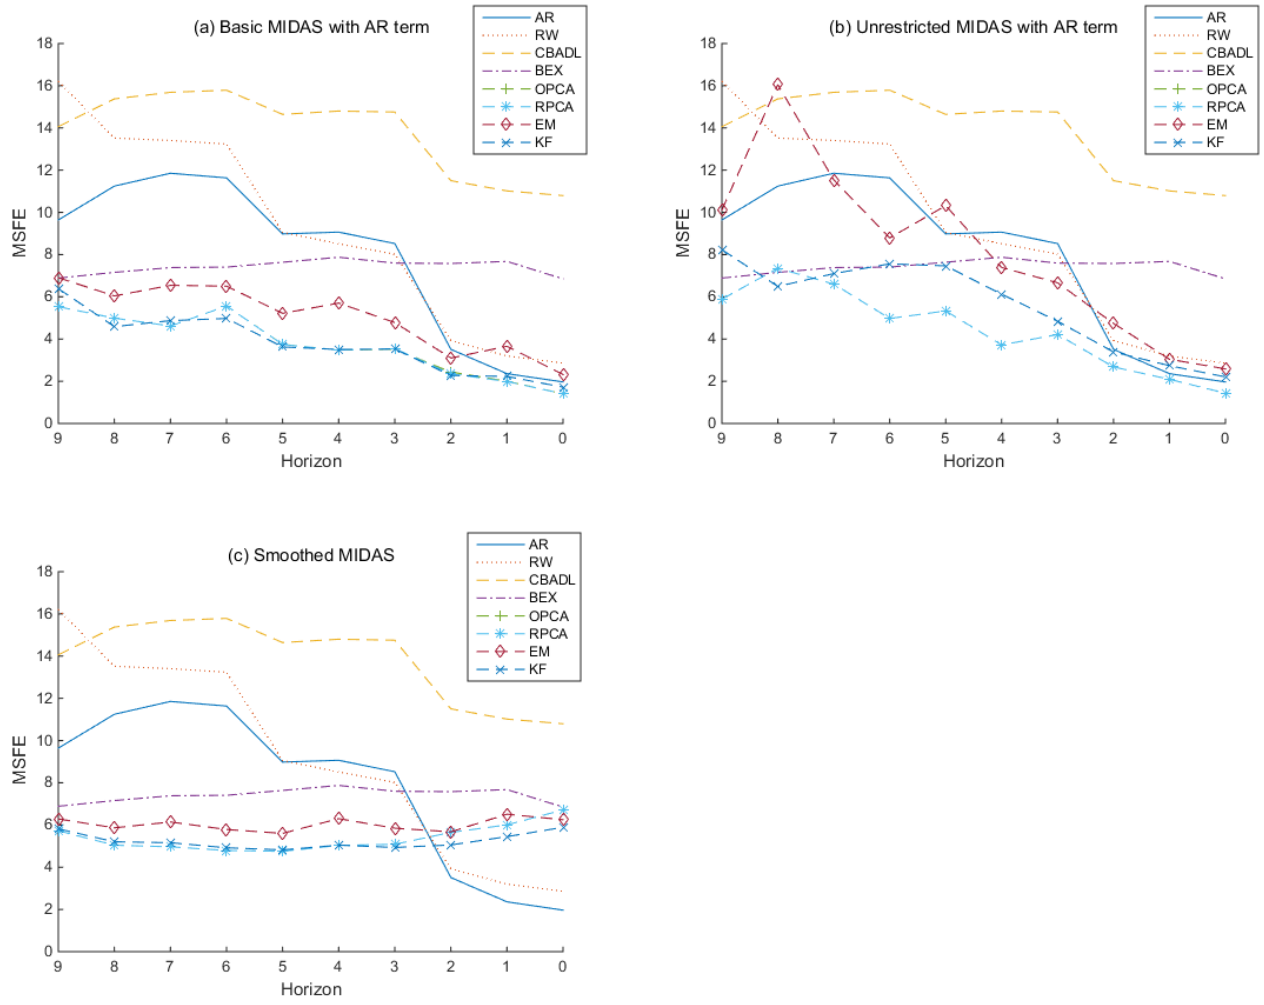
* Notes: See the Notes to Figure 6.

Figure 9: MSFEs of Factor-MIDAS Models with One Factor ($r = 1$)*



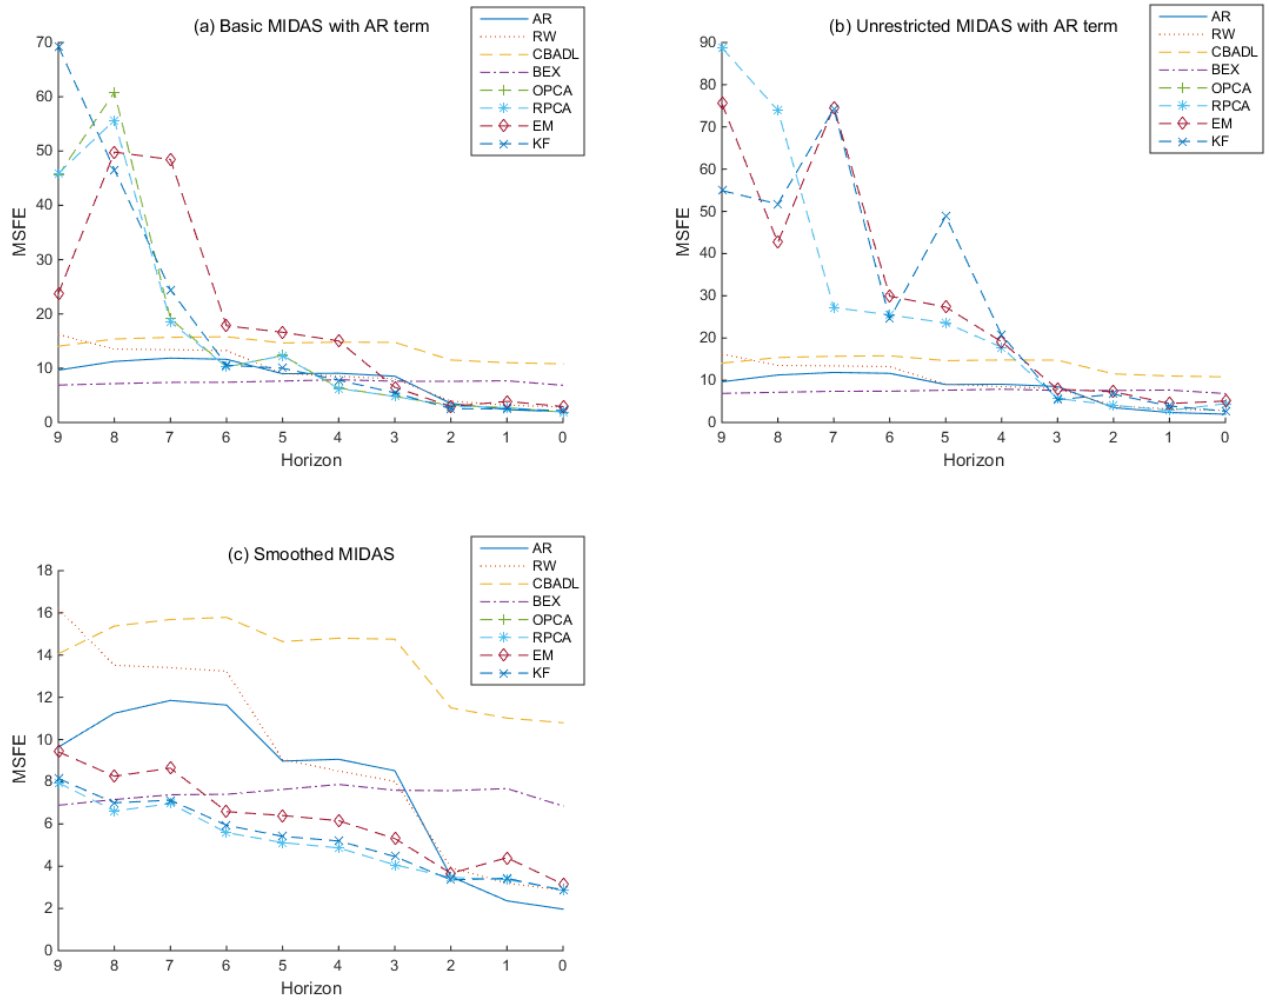
* Notes: See the Notes to 6.

Figure 10: MSFEs of Factor-MIDAS Models with with Two Factors ($r = 2$)*



* Notes: See the Notes to 6.

Figure 11: MSFEs of Factor-MIDAS Models with with Six Factors, $(r = 6)$*



*Notes: See the Notes to 6.
